Miami, FL 33199 <http://serc.fiu.edu/wqmnetwork/>

1. EXECUTIVE SUMMARY

This report summarizes the existing data from the FIU Coastal Water Quality Monitoring Network for calendar year January 1 – December 31, 2007. This includes water quality data collected from 28 stations in Florida Bay, 22 stations in Whitewater Bay, 25 stations in Ten Thousand Islands, 25 stations in Biscayne Bay, 49 stations on the Southwest Florida Shelf (Shelf), and 28 stations in the Cape Romano-Pine Island Sound area. Each of the stations in Florida Bay were monitored on a monthly basis with monitoring beginning in March 1991; Whitewater Bay monitoring began in September 1992; Biscayne Bay monthly monitoring began September 1993; the SW Florida Shelf was sampled quarterly beginning in spring 1995; and monthly sampling in the Cape Romano-Pine Island Sound area started January 1999.

Effective Oct. 1, 2007, the SFWMD contract deleted field sampling and lab analyses at 4 sites in Whitewater Bay area #31, 45, 46, and 50; 5 sites in Ten Thousand Islands #51, 60, 62, 68, and 73; 6 sites in Biscayne Bay #103, 109, 113, 116, 126, and 132; and all 49 sites on the SW Florida Shelf. Also effective Oct. 1, 2007 as per SFWMD contract, no samples were analyzed for silicate and field duplicates were reduced to 10% of sites collected.

Trend analysis is an ongoing process; ecosystems change with climate and management strategy, therefore, analytical results may change as more data is collected. It is also important to understand that trend analysis alone will not necessarily provide cause and effect relationships. One of the purposes of any monitoring program should be to use the data gained by routine sampling to extend our understanding of the system by developing new hypotheses as to the underlying driving processes. Much inference into the behavior of South Florida estuaries can be made from the observed magnitude and distribution of water quality parameters. This type of multivariate approach should prove useful to scientists and managers faced with the task

of interpreting large water quality datasets. This monitoring program has been very useful in helping to define restoration targets and will be even more valuable in determining whether these goals are met.

Climatological Conditions

Climate variability has major effects on the health of South Florida ecosystems because precipitation, temperature, evaporation and wind-driven water flow affect circulation, salinity, water exchange and biogeochemical processes. Furthermore, in a significant proportion water flow from Everglades managed canals partially follow precipitation cycles contributing further to complexity in response from coastal waters. Precipitation on the region has not been uniform over the data collection period of record, neither in space nor in time. 2007 was an average precipitation year from Palm Beach south, but the northern watershed, including Lake Okeechobee itself, experienced an extreme drought. This unusual dry year forced the SFWMD to curtail water supply to South Florida ecosystems, especially affecting those stations influenced by the Loxahatchee. Dryness plus reduced canal flows significantly affected the SW Florida coast during 2007. Precipitation in the Everglades rebounded from the drought of the late 1980's and reached levels equal or greater than the long term average (1949-2007; 141.68 cm yr⁻¹) for 10 of the last 17 years. Total precipitation for 2007 was 150.27 cm yr⁻¹ making it equal to the median value year since 1991. Nevertheless, July and August were above their respective medians by about 11 cm.

Florida Bay

The main external influences on water quality in Florida Bay are water exchange with the Gulf of Mexico at the western boundary, atmospheric precipitation, and terrestrial input from Taylor Slough and C-111 panhandle. The two largest impacts cannot be managed by man and even freshwater inputs from land are highly tied to climactic conditions and events.

Eastern Bay: Salinity was higher in the early months due to the drier than normal dry season. This points out the impact that the long water residence time has on Eastern Bay. Temperature, dissolved oxygen (DO), and turbidity were unremarkable. Nitrate (NO₃⁻) was higher than normal especially for the summer months. Ammonium (NH₄⁺) was higher than the grand median for the first half of the year and then rapidly declined to below average levels during

August. Total Phosphorus (TP) was elevated in Eastern Bay throughout most of the year as a result of the previous hurricane and road construction interaction (Rudnick et al. 2006). Chlorophyll *a* (CHLA) showed an inverse pattern to the dissolved inorganic nitrogen (DIN) pool, being highest in the wet season. Total organic nitrogen (TON) and total organic carbon (TOC) were lower than the grand median being indicative of temporal trend towards lower concentration.

Central Florida Bay: Salinity was higher in the early months due to the drier than normal dry season and was also high in Sep.-Nov. This points out the impact that the long water residence time has on Central Bay. Temperature was unremarkable; DO showed deviations from long term median possibly as a function of CHLA fluctuations. NO_3^- was normal except for large increases in Nov.-Dec. NH_4^+ was significantly below average for the year. TP was slightly lower during the wet season than other years. CHLA was high early in the year but declined to normal levels for the remainder. TOC and TON were higher in the winter-spring and lower than normal for rest of the year. pH in Central Bay was elevated relative to other years but unrelated to salinity. Turbidity was lower for 2007 as well.

Western Florida Bay: Salinity was slightly higher than usual but probably not significantly so. Temperature and DO were unremarkable. NO_3^- , NH_4^+ , and TP were normal for Western Bay. Turbidity and CHLA were generally lower than normal.

Whitewater Bay-Ten Thousand Islands Region

The influence of freshwater input from the Everglades Shark Slough is very influential to water quality of this region. Large salinity variations are the norm, being driven by both climactic events and water management practices. Although 2007 was relatively typical rainfall year, salinity patterns were generally not different from the grand medians. The exception was Whitewater Bay which exhibited elevated salinities until the onset of the wet season.

The influence of freshwater input from the Everglades is very significant to this region. Large salinity variations are the norm, being driven by both climactic events and water management practices. Although 2007 was relatively normal rainfall year, salinity patterns were elevated from the grand medians during the early part of the year and were higher than normal during the wet season.

Whitewater Bay: Salinity was elevated relative to long term median. Temperature, DO, and pH were unremarkable with values generally fluctuating around the median. NO_3^- , NH_4^+ , and TP concentrations were elevated while TON was reduced. TON was lower than the grand median. This is the result of the system-wide long term decline in TON output from the Everglades. TOC was slightly lower for most areas. CHLA varied seasonally and was more volatile than the median.

Mangrove Rivers: Salinity fluctuated widely due to freshwater inputs from Shark Slough but was slightly higher than usual. Temperature and pH were unremarkable with values generally fluctuating around the median. DO was generally higher than normal as was turbidity. Some peaks in NO_3^- , NH_4^+ , and TP were observed. TON was lower than the grand median. CHLA was lower in the dry season but came up to normal levels for the rest of the year.

Inner Waterway: Salinity fluctuated widely due to freshwater inputs from Shark Slough but was higher than usual. Temperature, DO, and pH were unremarkable with values generally fluctuating around the median. NO_3^- , NH_4^+ , and TP were all higher than the norm during the wet season. TON was lower than the grand median. CHLA showed a large peak in Jan. and Oct. but was normal for the rest of the year.

Blackwater River: Salinity was elevated relative to long term median and showed a rapid decline in Sep with a quick rebound in Oct. Temperature, DO, turbidity, and pH were unremarkable with values generally fluctuating around the median. Large peaks in NO_3^- , NH_4^+ , and TP were observed in Apr. and Oct. TON was lower than the grand median. CHLA was lower in the dry season but varied widely for the rest of the year.

Biscayne Bay

Salinity in Biscayne Bay is strongly modulated by its large tidal exchange with the ocean. Nevertheless, canal inputs do have a significant impact on the ecosystem, as evidenced by the reduced nearshore salinity patterns (Caccia and Boyer 2005). The largest intra-annual variations in salinity in this area are typically driven by freshwater releases from the canal system. Nutrient loads and concentrations in Biscayne Bay are strongly driven by canal inputs (Caccia and Boyer 2007). Therefore, precipitation patterns have a great impact on the bay both directly and indirectly.

Alongshore Zone: Because 2007 was a “normal” water year, salinity was generally similar to the long term median. Temperature and DO were unremarkable but both turbidity and pH showed large fluctuations, primarily in the dry season. The Oct. drop in salinity coincided with large increases in NO_3^- , NH_4^+ , TON, and TP as we have observed in other years. CHLA remained lower than the long term median.

Inshore Zone: Because the Inshore Zone is a continuation of the offshore gradient, trends were very similar to those observed for the Alongshore Zone. Temperature and DO were unremarkable but both turbidity and pH showed large fluctuations, primarily in the dry season. The Oct. drop in salinity coincided with large increases in NO_3^- , NH_4^+ , TON, and TP as we have observed in other years. CHLA remained lower than the long term median.

Main Bay: Fluctuations in water quality in the Main Bay were damped by its large volume and short residence time due to oceanic mixing. Salinity, temperature, DO, nutrients, and CHLA were all very similar to the grand median.

South Card Sound: Water quality in Card Sound was characterized by a large peak in Oct.-Nov. of NO_3^- , TON, TP, CHLA and turbidity. We are unsure as to what caused this anomaly as there was no concurrent change in salinity to suggest terrestrial input. One of the reasons for this may have been the advection of the Florida Bay bloom organisms to this part of Biscayne Bay by wind forcing, but there is no circulation data to support this. Other than that event, water quality was similar to long term median values.

North Bay: The North bay is the most compartmentalized and urbanized area of Biscayne Bay. As such nutrients tend to be higher in this region. Because 2007 was a “normal” water year, salinity was generally similar to the long term median. Temperature and DO were unremarkable but turbidity showed large increase in the fall while pH dropped in early spring. Large variations in NO_3^- , NH_4^+ , TON, TP, and CHLA occurred throughout the year, often being temporally unrelated. As such, it is difficult to assign a cause to these fluctuations.

Southwest Florida Shelf

Since this component of the monitoring program began in 1995 and is only sampled quarterly, there is not as much trend data to analyze as for other components. Although these analyses are preliminary it is possible to speculate that the clusters are formed as a function of hydrology and circulation patterns. We believe that the most inshore area clearly shows the

input of freshwater from Shark River being transported south and east around the Cape. Water overlying the northern shoal stations probably originates somewhere in or north of the Ten Thousand Islands. Our level of resolution is very low due to the limited numbers of sampling events and by the relatively large spatial gap between coastal and Shelf sampling sites. A better understanding of local circulation patterns in addition to increased density and frequency of sampling in the nearshore region may help define the coupling between freshwater inflow and Shelf water quality

Shark Zone: Because 2007 was a “normal” water year, salinity was generally similar to the long term median. Temperature and turbidity were unremarkable but DO, pH, TON, and CHLA were low. NO_3^- , NH_4^+ , and TP were similar to other years. CHLA remained lower than the long term median.

Shelf Zone: Because the Shelf Zone is a continuation of the offshore gradient, trends were very similar to those observed for the Shark Zone. Fluctuations in water quality on the Shelf were damped by its large volume mixing with the Gulf of Mexico. Only DO, turbidity, pH, and CHLA deviated from the median being lower than usual.

Shoal Zone: The Shoal area nearest the Ten Thousand Islands also showed similarities to the other SW Shelf sites with DO, turbidity, and pH being lower than usual. However, CHLA levels were more representative of long term median.

Cape Romano-Pine Island Sound

Overall, this part of coastal Florida has significantly higher concentrations of CHLA, TP, and DIN than the rest of the Ten Thousand Islands stations. Much of this is due to geological changes from carbonate rocks to silicates, which facilitates transport of phosphorus, and to major land use changes from the Big Cypress National Preserve to suburban and agricultural.

The largest intra-annual variations in salinity and water quality in this area are driven by freshwater releases from the Caloosahatchee River at Franklin Lock (S-79 water control structure) and associated pathways. This is due to the need to lower the water table inland because of potential flooding from hurricanes and to lower the Lake Okeechobee because of structural problems with the Hover Dike. Releases were minimal this year due to the drought in central Florida.

Marco Island: Salinities remained high all year reflecting the drought conditions in the watershed. Variations in temperature, DO pH, and TON were unremarkable as compared to long term median. TOC was lower than average due to low freshwater inputs. NO_3^- and NH_4^+ were highly variable and did not seem to be driven by freshwater inputs. TP was higher than average in the dry season and lower in the wet season. CHLA was lower than usual but peaked in the fall.

Rookery Bay: Salinities remained high all year reflecting the drought conditions in the watershed. Temperature, DO, pH, TON, and TP were unremarkable as compared to long term median. None of the measured variables help explain why pH dropped to 7.4 in May. TOC was lower than average due to low freshwater inputs but mirrored the annual pattern. NO_3^- , NH_4^+ , and turbidity were highly variable and did not seem to be driven by freshwater inputs. CHLA was generally lower than usual.

Naples Bay: Salinity was marginally higher in the fall but was not different for the bulk of the year. Temperature, TON, and TP were unremarkable as compared to long term median. pH was higher than normal and also highly variable. DO was slightly higher than usual while NO_3^- and CHLA were down. Turbidity, pH, and NH_4^+ were highly variable but did not seem to be driven by freshwater inputs. CHLA was generally lower than usual.

San Carlos Bay: This is the region most affected by Lake Okeechobee water releases through the Caloosahatchee River (S-79). The drought of 2007 was reflected in the high salinities throughout the region. We did not observe the usual 10-15 psu drop during the wet season nor the concomitant increase in NO_3^- . Temperature, DO, and TON were unremarkable as compared to long term median. Turbidity, NO_3^- , TP, TOC, and CHLA were generally lower than usual, especially during the wet season. NH_4^+ was highly variable and did not seem to be driven by freshwater inputs.

Estero Bay: Salinity was relatively invariant during 2007 and did not show the usual decline during the wet season. Temperature, TON, TP, and TOC were unremarkable as compared to long term median. DO was slightly elevated while pH was higher than normal in the spring-summer. Turbidity, NO_3^- , TOC, and CHLA were generally lower than usual, especially during the wet season. Peaks in CHLA sometimes corresponded with peaks in TP and NH_4^+ . TP was higher in the first 8 months and then declined to below the average. NH_4^+ was highly variable and did not seem to be driven by freshwater inputs.

Pine Island Sound: Salinity was relatively invariant during 2007 and did not show the usual decline during the wet season. Temperature, NO_3^- , TON, and TP were unremarkable as compared to long term median. DO was elevated for the first 2 months then declined to usual levels. pH was generally lower than normal but peaked in May for no obvious reason. Turbidity was higher during the summer but quickly dropped to very low levels in Sept.-Dec. NH_4^+ was highly variable and did not seem to be driven by freshwater inputs. TOC and CHLA were generally lower than usual, especially during the wet season. Peaks in CHLA sometimes corresponded with peaks in TP and NH_4^+ .

Cocohatchee River: Like the Caloosahatchee, the Cocohatchee River at Wiggins Pass was under low flow conditions due to the drought. Salinity dipped only slightly during the wet season in contrast to the large declines usually observed. We did not observe the usual 20-25 psu drop during the wet season or the concomitant increase in NO_3^- , NH_4^+ and TOC. Most all water quality variables were lower than the long term median with the exception of pH and DO which were higher.

Acknowledgements

We thank all of our many field personnel, laboratory technicians, and data support staff for their diligence and perseverance in this ongoing program, especially Pete Lorenzo. This project was possible due to the continued funding by the South Florida Water Management District (District Contract No. 4600000352). We also thank Vickie McGee at Rookery Bay NERR, the captain and crew of the R/V Bellows of the Florida Institute of Oceanography, and Everglades National Park Interagency Science Center for their field support of the monitoring program.

This report is contribution #T-384 of the Southeast Environmental Research Center at Florida International University.

2. PROJECT BACKGROUND

One of the primary purposes for conducting long-term monitoring projects is to be able to detect trends in the measured parameters over time. These programs are usually initiated as a response to public perception (and possibly some scientific data) that “the river-bay-prairie-forest-etc. is dying”. In the case of Florida Bay, the major impetus was the combination of a seagrass die-off, increased phytoplankton abundance, sponge mortality, and a perceived decline in fisheries beginning in 1987. In response to these phenomena, a network of water quality monitoring stations was established in 1989 to explicate both spatial patterns and temporal trends in water quality in an effort to elucidate mechanisms behind the recent ecological change.

This report summarizes the existing data from our South Florida Coastal Water Quality Monitoring Network through December 31, 2007 (Fig. 1.1). This network includes water quality data collected from 28 stations in Florida Bay, 22 stations in Whitewater Bay to Lostmans River, 25 stations in Ten Thousand Islands, 25 stations in Biscayne Bay, 49 stations on the Southwest Florida Shelf (Shelf), and 28 stations in the Cape Romano-Pine Island Sound area.

Each of the stations in Florida Bay were sampled on a monthly basis with monitoring beginning in March 1991 (except stations 14, 19, 22, and 23 which began April 1991). In July 1992, stations 25 through 28 were added in Florida Bay. Monthly sampling at stations 29-50 in Whitewater Bay were added to the monitoring program in September 1992. Biscayne Bay monthly monitoring began September 1993 for stations 100-125. In May 1996 an analysis of the data was performed to address the adequacy of spatial coverage. At that time, 10 station locations in the Biscayne Bay monitoring network were moved to provide coverage of North Biscayne Bay. The Ten Thousand Islands sites 51-75 were begun in Sept. 1994, the Shelf was sampled quarterly beginning in spring 1995, and the Cape Romano-Pine Island Sound area was started Jan. 1999. A summary of station locations and sampling period of record is shown in Table 1.

Figure 1.1. Fixed station locations for the SFWMD funded portion of the South Florida Coastal Water Quality Monitoring Network.

3. METHODS

Water samples were collected and analyzed using standard methodology outlined in the Quality Assurance Plan with prior approval from SFWMD and FDEP. Salinity, temperature (°C), dissolved oxygen (DO, mg l⁻¹), and pH were measured 10 cm below the surface and 10 cm above the bottom using a combination sonde (YSI 600XL). Sondes were calibrated prior to and after sampling to ensure accuracy.

Duplicate, unfiltered water samples were collected from 10 cm below the surface using sample rinsed 120 ml HDPE bottles and kept at ambient temperature in the dark during transport. Duplicate water samples for dissolved nutrient analysis were collected using sample rinsed 150 ml syringes. These samples were filtered by hand (25 mm glass fiber GF/F) into acetone-washed and sample rinsed 60 ml HDPE bottles, which were then capped and immediately placed on ice in the dark for transport. The wet filters, used for chlorophyll *a* analysis (CHLA), were placed in 2 ml plastic centrifuge tubes to which 1.5 ml of 90% acetone was added. They were then immediately capped and put into a dark bottle on ice for transport (APHA 1999).

Unfiltered water samples were analyzed for total organic carbon (TOC), total nitrogen (TN), total phosphorus (TP), alkaline phosphatase activity (APA), and turbidity (NTU). TOC was measured by direct injection onto hot platinum catalyst in a Shimadzu TOC-5000 after first acidifying to pH<2 and purging with CO₂-free air. TN was measured using an ANTEK 7000N Nitrogen Analyzer using O₂ as carrier gas instead of argon to promote complete recovery of the nitrogen in the water samples (Frankovich and Jones 1998). TP was determined using a dry ashing, acid hydrolysis technique (Solorzano and Sharp 1980). The APA assay measures the activity of alkaline phosphatase, an enzyme used by bacteria to mineralize phosphate from organic compounds (Hashimoto et al. 1985). This assay is performed by adding a known concentration of an organic phosphate compound (o-methylfluorescein phosphate) to an unfiltered water sample. Alkaline phosphatase in the water sample cleaves the phosphate, leaving o-methylfluorescein, a highly fluorescent compound. The fluorescence of initial and 2 hr incubations were measured using a Gilford Fluoro IV spectrofluorometer (excitation = 430 nm, emission = 507 nm) and subtracted to give APA (μM h⁻¹). APA measurements were discontinued after Sept. 30, 2006 at the request of SFWMD. Turbidity was measured using an HF Scientific model DRT-15C turbidimeter and reported in NTU.

Filtrates were analyzed for soluble reactive phosphorus (SRP), nitrate + nitrite (NO_x^-), nitrite (NO_2^-), ammonium (NH_4^+), and silicate (SiO_2) by flow injection analysis (Alpkem model RFA 300). Filters for CHLA content ($\mu\text{g l}^{-1}$) were allowed to extract for a minimum of 2 days at -20°C before analysis. Extracts were analyzed using a Gilford Fluoro IV Spectrofluorometer (excitation = 435 nm, emission = 667 nm) and compared to a standard curve of pure CHLA (Sigma).

Some parameters were not measured directly, but were calculated by difference. Nitrate (NO_3^-) was calculated as $\text{NO}_x^- - \text{NO}_2^-$. Dissolved inorganic nitrogen (DIN) was calculated as $\text{NO}_x^- + \text{NH}_4^+$. Total organic nitrogen (TON) was defined as $\text{TN} - \text{DIN}$. Concentrations for all of these water quality variables are reported in units of milligrams per liter (mg l^{-1}) or the equivalent parts per million (ppm), except where noted. All nutrient concentrations are based on the atomic weight of primary nutrient species (ppm-N, ppm-P, and ppm-C), not the molecular weight. All N:P ratios discussed are calculated on a molar basis.

3.1. LABORATORY ANALYSIS QUALITY CONTROL

All laboratory QC data and results are included as a separate Project QA report file on the CD. This report includes discussion on the following topics:

3.1.1. ACCURACY AND PRECISION

3.1.2. CALIBRATION DATA

3.1.3. PROBLEMS

3.1.4. SOLUTION TO PROBLEMS

3.1.5. EFFECTS OF THE RESULT ANALYSIS DATE-TIME

3.1.6. ALL QC PROBLEMS AND LISTING OF AFFECTED SAMPLES

3.2. FIELD MONITORING PROBLEMS

All field monitoring QC data and results are included as a separate Project QA report file on the CD. This report includes discussion on the following topics:

3.2.1. WEATHER RELATED ISSUES

3.2.2. EQUIPMENT FAILURES

3.2.3. SCHEDULING PROBLEMS

3.2.4. OTHER

3.3. STATISTICAL ANALYSIS

3.3.1. DISCUSSION

3.3.1.1. OBJECTIVE CLASSIFICATION ANALYSIS

Stations were stratified according to water quality characteristics (i.e. physical, chemical, and biological variables) using a statistical approach. Multivariate statistical techniques have been shown to be useful in reducing a large data set into a smaller set of independent, synthetic variables that capture much of the original variance. The method we chose was a type of objective classification analysis (OCA) which uses principal component analysis (PCA) followed by k-means clustering algorithm to classify sites as to their overall water quality. This approach has been very useful in understanding the factors influencing nutrient biogeochemistry in Florida Bay (Boyer et al., 1997), Biscayne Bay, and the Ten Thousand Islands (Boyer 2006). We have found that water quality at a specific site is the result of the interaction of a variety of driving forces including oceanic and freshwater inputs/outputs, sinks, and internal cycling.

Briefly, data were first standardized as Z-scores prior to analysis to reduce artifacts of differences in magnitude among variables and to convert values to deviations from the mean and express them as multiples of standard deviation. PCA was used to extract statistically significant composite variables (principal components) from the original data (Overland and Preisendorfer 1982). The PCA solution was rotated (using VARIMAX) in order to facilitate the interpretation of the principal components and the factor scores were saved for each data record. Both the mean and SD of the factor scores for each station over the entire period of record were then used as independent variables in a cluster analysis (k-means algorithm) in order to aggregate stations into groups of similar water quality. The purpose of this analysis was to collapse the 154 stations into a few groups which could then be analyzed in more detail.

3.3.1.2. BOX AND WHISKER PLOTS

Typically, water quality data are skewed to the left (low concentrations and below detects) resulting in non-normal distributions. Therefore it is more appropriate to use the median as the measure of central tendency because the mean is inflated by high outliers (Christian et al. 1991). Data distributions of water quality variables are reported as box-and-whiskers plots. The box-and-whisker plot is a powerful statistic as it shows the median, range, the data distribution as well as serving as a graphical, nonparametric ANOVA. The center horizontal line of the box is the median of the data, the top and bottom of the box are the 25th and 75th percentiles (quartiles), and the ends of the whiskers are the 5th and 95th percentiles. The notch in the box is the 95% confidence interval of the median. When notches between boxes do not overlap, the medians are considered significantly different. Outliers (<5th and >95th percentiles) were excluded from the graphs to reduce visual compression. Differences in variables were also tested between groups using the Wilcoxon Ranked Sign test (comparable to a *t*-test) and among groups by the Kruskal-Wallis test (ANOVA) with significance set at $P < 0.05$.

3.3.1.3. CONTOUR MAPS

In an effort to elucidate the contribution of external factors to the water quality of the region and to visualize gradients in water quality over the region, we combined data from other portions of our water quality monitoring network including the Florida Keys national Marine Sanctuary (<http://serc.fiu.edu/wqmnetwork/CONTOUR%20MAPS/ContourMaps.htm>). Data from these additional stations were collected during the same month as the SFWMD surveys and analyzed by the SERC laboratory using identical methods. Contour maps were produced using Surfer (Golden Software). The most important aspect of generating contour maps is the geostatistical algorithm used for interpolating the data values. Care should be taken in the selection of the algorithm because automated interpolation to a regular rectangular grid can produce artifacts, especially around the edges and when the area of interest is irregularly shaped. The kriging algorithm was used because it is designed to minimize the error variance while at the same time maintaining point pattern continuity (Isaaks & Srivastava, 1989). Kriging is a global approach which uses standard geostatistics to determine the "distance" of influence around each point and

the "clustering" of similar samples sites (autocorrelation). Therefore, unlike the inverse distance procedure, kriging will not produce valleys in the contour between neighboring points of similar value.

3.3.2. SOFTWARE USED

Data were analyzed using Statview (SAS), JMP (SAS), and SURFER (Golden Software).

3.3.3. GRAPHICAL TREND ANALYSIS

Times series were plotted by zone as medians of monthly data for the complete period of record to illustrate any temporal trend that might have occurred. Secular trends were quantified by simple regression with significance set at $P < 0.05$.

4. RESULTS AND DISCUSSION

4.1. REGIONAL CLIMATOLOGY

Climate variability has major effects on the health of South Florida ecosystems because precipitation, temperature, evaporation and wind-driven water flow affect circulation, salinity, water exchange and biogeochemical processes. Furthermore, in a significant proportion water flow from Everglades managed canals partially follow precipitation cycles contributing further to complexity in response from coastal waters. Precipitation on the region has not been uniform over the data collection period of record, neither in space nor in time. 2007 was an average precipitation year from Palm Beach south, but the northern watershed, including Lake Okeechobee itself, experienced an extreme drought (Fig. 4.1.2). This unusual dry year forced the SFWMD to curtail water supply to South Florida ecosystems, especially affecting those stations influenced by the Loxahatchee. Dryness plus reduced canal flows significantly affected the SW Florida coast during 2007. Precipitation in the Everglades (Royal Palm) rebounded from the drought of the late 1980's and reached levels equal or greater than the long term average (1949-2007; $141.68 \text{ cm yr}^{-1}$) for 10 of the last 17 years (Fig 4.1.3). Total precipitation for 2007 was $150.27 \text{ cm yr}^{-1}$ making it equal to the median value year since 1991. Nevertheless, July and August were above their respective medians by about 11 cm.

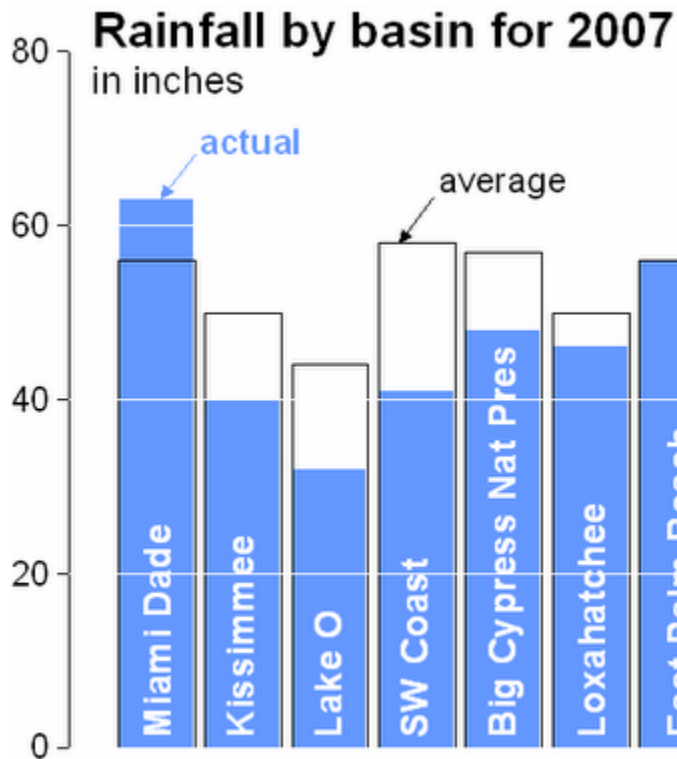

Figure 4.1.2. Precipitation of Central and South Florida (modified from Sobczak 2008)

4.2.STATE OF WATER QUALITY IN FLORIDA BAY

Overall Period of Record

Effective Oct. 1, 2007 as per SFWMD contract, no samples were analyzed for silicate and field duplicates were reduced to 10% of all sites collected.

The main external influences on water quality in Florida Bay are water exchange with the Gulf of Mexico at the western boundary, atmospheric precipitation, and terrestrial input from Taylor Slough and C-111 panhandle (Rudnick et al. 1999). The two largest impacts cannot be managed by man and even freshwater inputs from land are highly tied to climactic conditions and events.

A spatial analysis of data from our monitoring program resulted in the delineation of 3 groups of stations, which have robust similarities in water quality (Fig. 4.1.1). We contend that these spatially contiguous groups of stations are the result of similar hydrodynamic forcing and processing of materials, hence we call them 'zones of similar influence'. The Eastern Bay zone acts most like a 'conventional' estuary in that it has a quasi-longitudinal salinity gradient caused by the mixing of freshwater runoff with seawater. In contrast, the Central Bay is a hydrographically isolated area with low and infrequent terrestrial freshwater input, a long water residence time, and high evaporative potential. The Western Bay zone is the most influenced by the Gulf of Mexico tides and is also isolated from direct overland freshwater sources.

Figure 4.1.1. Zones of similar water quality in Florida Bay

Early in the record, salinity and total phosphorus (TP) concentrations declined baywide while turbidity (cloudiness of the water) increased dramatically. The salinity decline in Eastern and Central Florida Bay was dramatic early on and has since stabilized into a regular seasonal cycle (Fig. 4.1.4-4.1.6). The box-and-whisker plots presented in this and following figures show the range (boxes are quartiles; whiskers include 90% of data) and median (line in box) of the monthly data. Some of this decrease in Eastern Bay could be accounted for by increased freshwater flows from the Everglades but declines in other areas point to the climactic effect of increased rainfall during this period. The Central Bay continues to experience hypersaline conditions (>35) during the summer but the extent and duration of the events is much shorter.

Chlorophyll *a* concentrations (CHLA), a proxy for phytoplankton biomass, were particularly dynamic and spatially heterogeneous (Fig. 4.1.6-4.1.6). The Eastern Bay generally has the lowest CHLA while the Central Bay is highest. In the Eastern Bay, which makes up roughly half of the surface area of Florida Bay, CHLA has declined by $0.9 \mu\text{g l}^{-1}$ or 63%. Most of this decline occurred over a few months in the spring/summer of 1994 and had remained relatively stable until the hurricanes of 2005. Since then a large cyanobacterial bloom has been present in this

region (Rudnick et al. 2006). The general consensus was that the bloom formed as a result of water management in response to hurricane activity and disturbance from road construction. The bloom declined in early 2007 but rebounded in the wet season.

The isolated Central Bay zone underwent a 5-fold increase in CHLA from 1989-94 then rapidly declined to previous levels by 1996. In Western Florida Bay, there was a significant increase in CHLA, yet median concentrations remained modest ($2 \mu\text{g l}^{-1}$) by most estuarine standards. There were significant blooms in Central and Western Bay immediately following Hurricanes Georges (Nov. 1998) but it was Hurricane Irene's large rainfall input (Oct. 1999) which spiked the largest blooms in this region of the bay. It is important to note that these changes in CHLA (and turbidity) happened years after the poorly-understood seagrass die-off in 1987. It is possible that the death and decomposition of large amounts of seagrass biomass might partially explain some of the changes in water quality of Florida Bay but the connections are temporally disjoint and the processes indirect and not well understood.

As mentioned previously, TP concentrations have declined baywide over the 14 year period of record (until the 2005 hurricane season). As with salinity, most of these declines occurred early in the record. Unlike most other estuaries, increased terrestrial runoff may have been partially responsible for the decrease in TP concentrations in the Eastern Bay. This is because the TP concentrations of the runoff are at or below ambient levels in the bay. It is also important to understand that almost all the phosphorus measured as TP is in the form of organic matter which is less accessible to plants and algae than inorganic phosphate. The elevated TP in the Central Bay is mostly due to concentration effect of high evaporation. Recently, there have been significant peaks during the fall season in both Eastern and Western Bays. The 2005 hurricane season impacted the Eastern Bay with large loading of TP. In addition, the US Route 1 road construction may have had an impact as well (Rudnick et al. 2006). TP has declined but remained elevated in Eastern Bay through 2007.

The dissolved inorganic nitrogen assemblage (DIN) is made up of ammonium (NH_4^+), nitrate (NO_3^-), and nitrite (NO_2^-). The Western Bay is lowest in DIN; phytoplankton in this region may be limited by N availability on a regular basis. DIN in the Eastern Bay is a little higher and is mostly in the form of NO_3^- while highest levels are found in the Central Bay as NH_4^+ .

Turbidity in the Central and Western Bays have increased greatly since 1991 (not shown). Turbidity in Eastern Bay increased 2-fold from 1991-93, while Central and Western Bays

increased by factors of 20 and 4, respectively. Turbidity across the bay has since stabilized and possibly declined but certainly not to previous levels. In general, the Eastern Bay has the clearest water, which is due to a combination of factors such as high seagrass cover, more protected basins, low tidal energy, and shallow sediment coverage. We are unsure as to the cause, but the loss of seagrass coverage may have destabilized the bottom so that it is more easily disturbed by wind events.

Eastern Florida Bay Zone

Western Florida Bay Zone

Figure 4.1.6. Box-and-whisker plots of water quality in Western Florida Bay by survey.

2007 Alone

The following Figures 4.1.7-4.1.9 show the monthly median of 2007 data from each zone compared to the long term median for each zone. We feel that this graphical approach is useful in pointing out anomalies and present some possible explanations for these differences.

2007 was a typical rainfall year (since 1991), however it showed higher salinity in the bay during the first few months than usual, perhaps caused by precipitation deficits (below grand median) for January, February, March, May, June and September. There were no direct hurricane impacts to Florida Bay during 2007.

Eastern Bay

Salinity was higher in the early months due to the drier than normal dry season (Fig 4.1.7). This points out the impact that the long water residence time has on Eastern Bay and the importance of rainfall. Temperature, DO, and turbidity were unremarkable. NO_3^- was higher than normal especially for the summer months (Fig 4.1.7). NH_4^+ was higher than the grand median for the first half of the year and then rapidly declined to below average levels during August. TP was elevated in Eastern Bay throughout most of the year as a result of the previous hurricane and road construction interaction (Rudnick et al. 2006). CHLA showed an inverse pattern to DIN, being highest in the wet season. TON and TOC were lower than the grand median being indicative of temporal trend towards lower concentration.

Central Bay

Salinity was higher in the early months due to the drier than normal dry season and was also high in Sep.-Nov. (Fig 4.1.8). This points out the impact that the long water residence time has on Central Bay. Temperature was unremarkable; DO showed deviations from long term median possibly as a function of CHLA fluctuations. NO_3^- was normal except for large increases in Nov.-Dec. (Fig 4.1.8). NH_4^+ was significantly below average for the year. TP was slightly lower during the wet season than other years. CHLA was high early in the year but declined to normal levels for the remainder. TOC and TON were higher in the winter-spring and lower than normal for rest of the year. pH in Central Bay was elevated relative to other years but unrelated to salinity. Turbidity was lower for 2007 as well.

Western Bay

Salinity was slightly higher than usual (Fig 4.1.9) but probably not significantly so. Temperature and DO were unremarkable. NO_3^- , NH_4^+ , and TP were normal for Western Bay. Turbidity and CHLA were generally lower than normal.

4.3. STATE OF WATER QUALITY IN WHITEWATER BAY - TEN THOUSAND ISLANDS COMPLEX

Overall Period of Record

As of Oct. 1, 2007 the SFWMD contract no longer includes sampling at 4 sites in Whitewater Bay area, # 31, 45, 46, and 50. As of Oct. 1, 2007 the SFWMD contract no longer includes sampling at 5 sites in Ten Thousand Islands area, #51, 60, 62, 68, and 73. Also effective Oct. 1, 2007 as per SFWMD contract, no samples were analyzed for silicate and field duplicates were reduced to 10% of all sites collected.

A spatial analysis of data from our monitoring program resulted in the delineation of 6 groups of stations, which have robust similarities in water quality (Fig. 4.2.1). The first cluster was composed of 13 stations in and around the Shark, Harney, Broad, and Lostmans Rivers and is called the Mangrove River (MR) group. This cluster also included a sampling station just off the Faka Union Canal. The second cluster was made up of the 8 stations enclosed within Whitewater Bay proper (WWB). Twelve stations were sited mostly in and around the coastal islands of TTI-WWB formed the Gulf Island group (GI). The water quality characteristics at the Coot Bay site (COOT) were sufficiently different so as to be a cluster of its own. The next cluster contained the northernmost 2 stations in the Blackwater River estuary (BLK). Finally, the Inland Wilderness Waterway zone (IWW) included 11 stations distributed throughout the inside passage as well as the Chatham River and the station off Everglades City.

Figure 4.2.1. Zones of similar water quality in Whitewater Bay-Ten Thousand Islands complex

Marked differences in physical, chemical, and biological characteristics among zones were illustrated by this technique. The general spatial trend is one of highly variable salinity as a result of Shark Slough inputs in the south (Fig. 4.1.2-4.1.6). Salinity in the Gulf Islands zone was more consistent due to Gulf of Mexico influence but also is affected by Caloosahatchee River outputs. CHLA concentrations were relatively high in this region compared to Florida Bay and the Shelf. Highest CHLA were observed in the semi-enclosed areas such as Whitewater Bay and the Inner Wilderness Waterway. It is possible that the longer water residence times exhibited in these areas promoted the intensification of algal biomass. TP tended to be lowest in Whitewater Bay and Mangrove Rivers but increased northward along the coast. The spatial distribution of DIN was generally opposite to that of TP. The net effect was the formation of a gradient with strong phosphorus limitation occurring in the southern region which shifted to a

more balanced N:P ratio in the northern area around the Blackwater River. The Mangrove Rivers were a significant source of TOC to the Shelf. TOC was highest in the south and declined northward along the coast.

We believe these gradients are the result of coastal geomorphology and watershed characteristics in the region. The width of the mangrove forest is widest in the south (15 km) but grades to only 4 km wide in the northern TTI; this being a function of elevation and sediment type. Whitewater Bay is a semi-enclosed body of water with a relatively long residence time, which receives overland freshwater input from the Everglades marsh. The long water residence time may explain the very low P concentrations (from biological uptake), while the high evaporation rate would tend to concentrate dissolved organic matter (DOM). The Mangrove Rivers are directly connected to the Shark River Slough and therefore have a huge watershed relative to their volume. Freshwater inputs from this source are very low in P while the extensive mangrove forest contributes much DOM. The Inner Waterway is an intermediate zone in all respects; having extensive channelization but low freshwater input. The Gulf Island zone has very low freshwater input due to the poorly drained watershed of the Big Cypress Basin. Instead of mangrove river channels there are many mangrove islands set in low tidal energy environment situated behind the Cape Romano Shoals. Finally there is the Blackwater River cluster with highest TP concentrations. There is considerable agriculture (tomatoes, etc.) in the Blackwater River watershed, which may contribute significant amounts of P to the system via drainage ditches. Further analysis of this relationship is planned.

Blackwater River Zone

Figure 4.2.6. Box-and-whisker plots of water quality in WWB-TTI by survey.

2007 Alone

The influence of freshwater input from the Everglades is very significant to this region. Large salinity variations are the norm, being driven by both climactic events and water management practices (Fig. 4.2.7-4.2.10). Although 2007 was relatively normal rainfall year, salinity patterns were elevated from the grand medians during the early part of the year and were higher than normal during the wet season, as result of precipitation deficits (below grand median) for January, February, March, May, June and September

Whitewater Bay

Salinity was elevated relative to long term median (Fig. 4.2.7). Temperature, DO, and pH were unremarkable with values generally fluctuating around the median. NO_3^- , NH_4^+ , and TP concentrations were elevated while TON was reduced. TON was lower than the grand median. This is the result of the system-wide long term decline in TON output from the Everglades. TOC was slightly lower for most areas. CHLA varied seasonally and was more volatile than the median.

Mangrove Rivers

Salinity fluctuated widely due to freshwater inputs from Shark Slough but was slightly higher than usual (Fig. 4.2.8). Temperature and pH were unremarkable with values generally fluctuating around the median. DO was generally higher than normal as was turbidity. Some peaks in NO_3^- , NH_4^+ , and TP were observed. TON was lower than the grand median. CHLA was lower in the dry season but came up to normal levels for the rest of the year.

Inner Waterway

Salinity fluctuated widely due to freshwater inputs from Shark Slough but was higher than usual (Fig. 4.2.9). Temperature, DO, and pH were unremarkable with values generally fluctuating around the median. NO_3^- , NH_4^+ , and TP were all higher than the norm during the wet season. TON was lower than the grand median. CHLA showed a large peak in Jan. and Oct. but was normal for the rest of the year.

Blackwater River

Salinity was elevated relative to long term median and showed a rapid decline in Sep with a quick rebound in Oct. (Fig. 4.2.10). Temperature, DO, turbidity, and pH were unremarkable with values generally fluctuating around the median. Large peaks in NO_3^- , NH_4^+ , and TP were observed in Apr. and Oct. TON was lower than the grand median. CHLA was lower in the dry season but varied widely for the rest of the year.

4.4. STATE OF WATER QUALITY IN BISCAYNE BAY

Overall Period of Record

As of Oct. 1, 2007 the SFWMD contract no longer includes sampling at 6 sites in Biscayne Bay #103, 109, 113, 116, 126, and 132. Also effective Oct. 1, 2007 as per SFWMD contract, no samples were analyzed for silicate and field duplicates were reduced to 10% of all sites collected.

A spatial analysis of data from our monitoring program resulted in the delineation of 6 groups of stations, which have robust similarities in water quality (Fig. 4.3.1). The first cluster was composed of 2 stations closest to the shore in the south Bay and was called the Alongshore group (AS). These are stations most influenced by the Goulds, Military and Mowry Canals. The second cluster was made up of the 5 stations farther from the coast called Inshore (IS). Thirteen stations situated mostly in the bay proper were called the main Bay (MAIN) group. The next cluster contained 3 stations situated in areas of great tidal exchange (ocean channel, not shown). Two stations in Card Sound grouped together SCARD. Finally, the Turkey Point station comprised its own cluster (not shown).

Figure 4.3.1. Zones of similar water quality in Biscayne Bay.

There was a gradient of increasing salinity with distance from the west coast of the Bay (AS < IS < MAIN clusters Fig. 4.3.2-4.3.6). Opposite to the salinity gradient, highest concentrations of CHLA, DIN, and TP were observed near the coast. This types of gradient are indicative of anthropogenic inputs. NBAY showed DIN levels comparable to the high concentrations seen AS but had a higher median salinity. In addition, NBAY had the highest median TP concentration of any zone. SCARD had relatively high DIN concentrations relative to the other nutrients. Some of this may be attributed to the long water residence time of this basin as evidence by near ocean salinities. TOC concentrations were highest in AS > IS > MAIN,

denoting a freshwater source (not shown). CHLA was low in most areas showing the same general gradient as TP. The cyanobacterial bloom in Eastern Florida Bay which had occasionally intruded into South Card Sound during 2006 was generally not an issue in 2007.

Alongshore Zone

Inshore Zone

Figure 4.3.3. Box-and-whisker plots of water quality in Biscayne Bay by survey.

Main Bay Zone

Figure 4.3.4. Box-and-whisker plots of water quality in Biscayne Bay by survey.

South Card Sound Zone

Figure 4.3.5. Box-and-whisker plots of water quality in Biscayne Bay by survey.

North Bay Zone

Figure 4.3.6. Box-and-whisker plots of water quality in Biscayne Bay by survey.

2007 Alone

Salinity in Biscayne Bay is strongly modulated by its large tidal exchange with the ocean. Nevertheless, canal inputs do have a significant impact on the ecosystem, as evidenced by the reduced nearshore salinity patterns (Caccia and Boyer 2005). The largest intra-annual variations in salinity in this area are typically driven by freshwater releases from the canal system. Nutrient loads and concentrations in Biscayne Bay are strongly driven by canal inputs (Caccia and Boyer 2007). Therefore, precipitation patterns have a great impact on the bay both directly and indirectly. Unexplained low pHs for March and April were observed baywide.

Alongshore Zone

Because 2007 was a “normal” water year, salinity was generally similar to the long term median (Fig. 4.3.7). Temperature and DO were unremarkable but both turbidity and pH showed large fluctuations, primarily in the dry season. The Oct. drop in salinity coincided with large increases in NO_3^- , NH_4^+ , TON, and TP as we have observed in other years. CHLA remained lower than the long term median.

Inshore Zone

Because the Inshore Zone is a continuation of the offshore gradient, trends were very similar to those observed for the Alongshore Zone (Fig. 4.3.8). Temperature and DO were unremarkable but both turbidity and pH showed large fluctuations, primarily in the dry season. The Oct. drop in salinity coincided with large increases in NO_3^- , NH_4^+ , TON, and TP as we have observed in other years. CHLA remained lower than the long term median.

Main Bay

Fluctuations in water quality in the Main Bay were damped by its large volume and short residence time due to oceanic mixing. Salinity, temperature, DO, nutrients, and CHLA were all very similar to the grand median (Fig. 4.3.9).

South Card Sound

Water quality in Card Sound was characterized by a large peak in Oct.-Nov. of NO_3^- , TON, TP, CHLA and turbidity. (Fig. 4.3.10) We are unsure as to what caused this anomaly as there

was no concurrent change in salinity to suggest terrestrial input. One of the reasons for this may have been the advection of the Florida Bay bloom organisms to this part of Biscayne Bay by wind forcing, but there is no circulation data to support this. Other than that event, water quality was similar to long term median values.

North Bay

The North bay is the most compartmentalized and urbanized area of Biscayne Bay. As such nutrients tend to be higher in this region (Fig. 4.3.11). Because 2007 was a “normal” water year, salinity was generally similar to the long term median. Temperature and DO were unremarkable but turbidity showed large increase in the fall while pH dropped in early spring. Large variations in NO_3^- , NH_4^+ , TON, TP, and CHLA occurred throughout the year, often being temporally unrelated. As such, it is difficult to assign a cause to these fluctuations.

4.5. STATE OF WATER QUALITY ON THE SW FLORIDA SHELF

Overall Period of Record

As of Oct. 1, 2007 the SFWMD contract no longer includes sampling of any of the 49 SW Shelf sites.

A spatial analysis of data from our monitoring program resulted in the delineation of 3 groups of stations, which have robust similarities in water quality (Fig. 4.4.1). The first cluster was composed of only 2 stations, which were closest to the shore off Cape Sable; they were called the SHARK group after the Shark River, the main source of freshwater to the region. The second cluster was made up of the 7 more northerly stations nearest the coast and called SHOAL. The remaining stations were called the SHELF group.

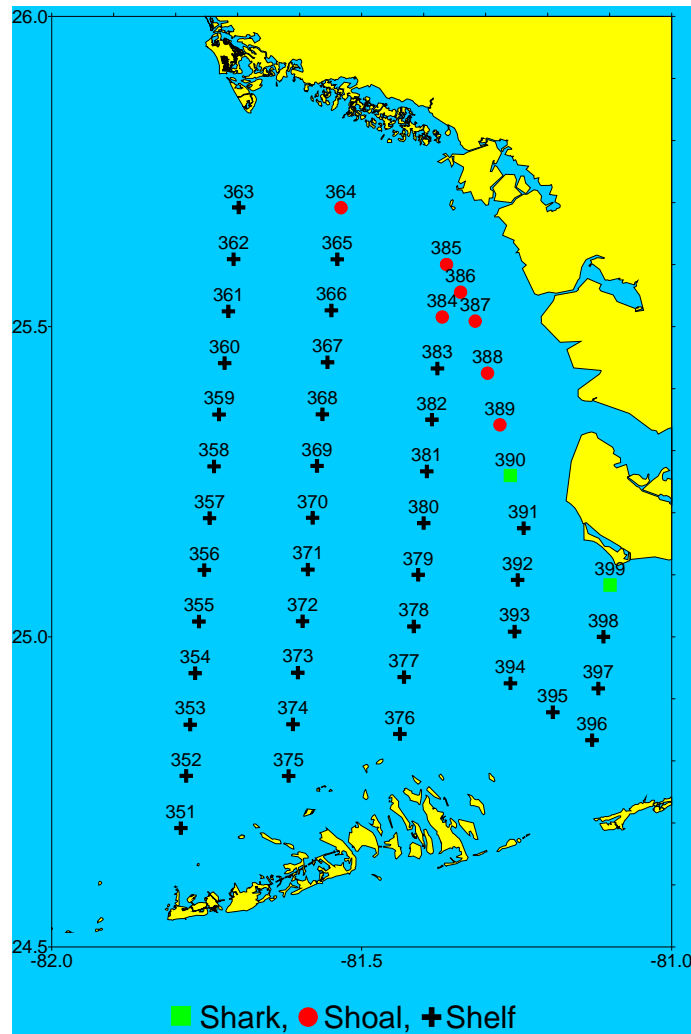

Figure 4.4.1. Zones of similar water quality on the SW Shelf.

Salinity is typically lowest in the SHARK zone as a result of its proximity to the Shark River/Everglades influence (Fig. 4.4.2-4.4.4). There is a decreasing concentration gradient of SHARK > SHOAL > SHELF for CHLA, TP, and TOC. It is clear that the SHARK stations have higher DIN concentrations while the SHOAL and SHELF stations were more similar.

The clustering is driven by hydrology and circulation patterns as related to nutrient gradients. The inshore cluster (SHARK) clearly shows the inputs of freshwater from Shark River being transported south and east around the Cape. Water overlying the Shoal stations probably originates somewhere in or north of the Ten Thousand Islands. Our level of resolution is low due to the limited numbers of sampling events and by the relatively large spatial gap between coastal and Shelf sampling sites. A better understanding of local circulation patterns in addition to increased density and frequency of sampling in the nearshore region may help define the coupling between freshwater inflow and Shelf water quality

Shark Zone

Figure 4.4.2. Box-and-whisker plots of water quality in SW Florida Shelf by survey.

Shelf Zone

Figure 4.4.3. Box-and-whisker plots of water quality in SW Florida Shelf by survey.

Shoal Zone

Figure 4.4.4. Box-and-whisker plots of water quality in SW Florida Shelf by survey.

2007 Alone

Since this component of the monitoring program began in 1995 and is only sampled quarterly, there is not as much trend data to analyze as for other areas. In addition, the SW Shelf sampling was cancelled as of Oct. 1, 2007 so no new data will be reported after Survey 49.

Shark Zone

Because 2007 was a “normal” water year, salinity was generally similar to the long term median (Fig. 4.4.5). Temperature and turbidity were unremarkable but DO, pH, TON, and CHLA were low. NO_3^- , NH_4^+ , and TP were similar to other years. CHLA remained lower than the long term median.

Shelf Zone

Because the Shelf Zone is a continuation of the offshore gradient, trends were very similar to those observed for the Shark Zone (Fig. 4.4.6). Fluctuations in water quality on the Shelf were damped by its large volume mixing with the Gulf of Mexico. Only DO, turbidity, pH, and CHLA deviated from the median being lower than usual.

Shoal Zone

The Shoal area nearest the Ten Thousand Islands also showed similarities to the other SW Shelf sites with DO, turbidity, and pH being lower than usual. However, CHLA levels were more representative of long term median.

Data, Graphs, and Figures

4.6. STATE OF WATER QUALITY IN THE CAPE ROMANO - PINE ISLAND SOUND AREA

Overall Period of Record

Effective Oct. 1, 2007 as per SFWMD contract, no samples were analyzed for silicate and field duplicates were reduced to 10% of all sites collected.

Because of the heterogeneous nature of the region, we used generally accepted geomorphological characteristics to group the stations (Fig. 4.5.1). These groupings are the Cocohatchee River at Wiggins Pass (COCO), Estero Bay (EST), Cape Romano-Marco Island (MARC), Naples Bay (NPL), Pine Island Sound (PIS), Rookery Bay (RB), and San Carlos Bay (SCB). SCB is located at the mouth of the Caloosahatchee River, a major managed outlet for freshwater from Lake Okeechobee.

Figure 4.5.1. Map of station locations in Cape Romano-Pine Island Sound area.

All zones experienced low salinity during the beginning of the wet season with the opening of the Caloosahatchee River at Franklin Lock (S-79 water control structure) (Fig. 4.5.2-4.5.8). CHLA is elevated in this area but not excessive when compared to the overall Ten Thousand Islands. SCB is most directly affected by the releases also had highest concentrations of TP, DIN, and TOC. Estero Bay also exhibited lower salinities than the other areas as a result of

freshwater input from the Estero and Imperial Rivers as well as Hendry Creek. EST is relatively enclosed, has a long water residence time, and is bordered on the north by the city of Ft. Meyers. These facts may account for the elevated CHLA, DIN and TP.

Overall, this area has significantly higher concentrations of CHLA, TP, and DIN than the bulk of the Ten Thousand Islands stations. Much of this is due to geological changes from carbonate to silicate bedrock, which facilitates transport of phosphorus, and to major land use changes from the Big Cypress National Preserve to suburban and agricultural. Except San Carlos Bay, all zone share common regime shift for TP in Oct-Nov 2002, when concentrations decreased drastically to gradually return to higher concentrations by 2006. These seem to be related to water management practices.

Cocohatchee River at Wiggins Pass

Figure 4.5.8. Single point times series of water quality in the Cocohatchee River by survey.

2007 Alone

The largest intra-annual variations in salinity and water quality in this area are driven by freshwater releases from the Caloosahatchee River at Franklin Lock (S-79 water control structure) and associated pathways (Fig. 4.5.8-4.5.14). This is due to the need to lower the water table inland because of potential flooding from hurricanes and to lower the Lake Okeechobee because of structural problems with the Hover Dike. Releases were minimal this year due to the drought in central Florida which caused record low levels in Lake Okeechobee. This added to the rainfall deficit resulted in water quality widely fluctuating and deviating from the grand median during year 2007.

Marco Island

Salinities remained high all year reflecting the drought conditions in the watershed. Variations in temperature, DO pH, and TON were unremarkable as compared to long term median (Fig. 4.5.8). TOC was lower than average due to low freshwater inputs. NO_3^- and NH_4^+ were highly variable and did not seem to be driven by freshwater inputs. TP was higher than average in the dry season and lower in the wet season. CHLA was lower than usual but peaked in the fall.

Rookery Bay

Salinities remained high all year reflecting the drought conditions in the watershed. Temperature, DO, pH, TON, and TP were unremarkable as compared to long term median (Fig. 4.5.9). None of the measured variables help explain why pH dropped to 7.4 in May. TOC was lower than average due to low freshwater inputs but mirrored the annual pattern. NO_3^- , NH_4^+ , and turbidity were highly variable and did not seem to be driven by freshwater inputs. CHLA was generally lower than usual.

Naples Bay

Salinity was marginally higher in the fall but was not different for the bulk of the year. Temperature, TON, and TP were unremarkable as compared to long term median (Fig. 4.5.10). pH was higher than normal and also highly variable. DO was slightly higher than usual while

NO_3^- and CHLA were down. Turbidity, pH, and NH_4^+ were highly variable but did not seem to be driven by freshwater inputs. CHLA was generally lower than usual.

San Carlos Bay

This is the region most affected by Lake Okeechobee water releases through the Caloosahatchee River (S-79). The drought of 2007 was reflected in the high salinities throughout the region (Fig. 4.5.11). We did not observe the usual 10-15 psu drop during the wet season nor the concomitant increase in NO_3^- . Temperature, DO, and TON were unremarkable as compared to long term median. Turbidity, NO_3^- , TP, TOC, and CHLA were generally lower than usual, especially during the wet season. NH_4^+ was highly variable and did not seem to be driven by freshwater inputs.

Estero Bay

Salinity was relatively invariant during 2007 and did not show the usual decline during the wet season (Fig. 4.5.12). Temperature, TON, TP, and TOC were unremarkable as compared to long term median. DO was slightly elevated while pH was higher than normal in the spring-summer. Turbidity, NO_3^- , TOC, and CHLA were generally lower than usual, especially during the wet season. Peaks in CHLA sometimes corresponded with peaks in TP and NH_4^+ . TP was higher in the first 8 months and then declined to below the average. NH_4^+ was highly variable and did not seem to be driven by freshwater inputs.

Pine Island Sound

Salinity was relatively invariant during 2007 and did not show the usual decline during the wet season (Fig. 4.5.13). Temperature, NO_3^- , TON, and TP were unremarkable as compared to long term median. DO was elevated for the first 2 months then declined to usual levels. pH was generally lower than normal but peaked in May for no obvious reason. Turbidity was higher during the summer but quickly dropped to very low levels in Sept.-Dec. NH_4^+ was highly variable and did not seem to be driven by freshwater inputs. TOC and CHLA were generally lower than usual, especially during the wet season. Peaks in CHLA sometimes corresponded with peaks in TP and NH_4^+ .

Cocohatchee River

Like the Caloosahatchee, the Cocohatchee River was under low flow conditions due to the drought. Salinity dipped only slightly during the wet season in contrast to the large declines usually observed (Fig. 4.5.14). We did not observe the usual 20-25 psu drop during the wet season nor the concomitant increase in NO_3^- , NH_4^+ and TOC. Most all water quality variables were lower than the long term median with the exception of pH and DO which were higher.

Data, Graphs, and Figures

All data for the period of record are available at:

<http://serc.fiu.edu/wqmnetwork/SFWMD-CD/DataDL.htm>

Contour maps showing spatial distributions of all measured variables (quarterly) are available at:

<http://serc.fiu.edu/wqmnetwork/SFWMD-CD/ContourMaps.htm>

5. CHANGES/UPDATES TO PREVIOUS REPORTS

The quarterly reports for Oct.-Dec., 2006 (188-190); Jan.-Mar., 2007 (191-193); Apr.-Jun., 2007 (194-196); Jul.-Sep., 2007 (197-199); and Oct.-Dec., 2007 (200-202) were revised to include the ADaPT electronic deliverables and expanded QA reports.
