We describe here the preparation and characterization of a photocathode assembly for CO₂ reduction to CO in 0.1 M LiClO₄ acetonitrile. The assembly was formed on 1.0 μm thick mesoporous films of NiO using a layer-by-layer procedure based on Zr(IV)–phosphonate bridging units. The structure of the Zr(IV) bridged assembly, abbreviated as NiO–DA–RuCP₂⁺–Re(I), where DA is the dianiline-based electron donor (N,N′,N′′,N″-(4(CH₂)₃PO₃H₂)₂–4,4′-dianiline), RuCP₂⁺ is the light absorber [Ru((4,4′-(PO₃H₂CH₂)₂–2,2′-bipyridine)(2,2′-bipyridine))₂]²⁺, and Re(I) is the CO₂ reduction catalyst, Re(I)((4,4′-PO₃H₂CH₂)₂–2,2′-bipyridine)(CO₂)Cl. Visible light excitation of the assembly in CO₂ saturated solution resulted in CO₂ reduction to CO. A steady-state photocurrent density of 65 μA cm⁻² was achieved under one sun illumination and an IPCE value of 1.9% was obtained with 450 nm illumination. The importance of the DA aniline donor in the assembly as an initial site for reduction of the RuCP₂⁺ excited state was demonstrated by an 8 times higher photocurrent generated with DA present in the surface film compared to a control without DA. Nanosecond transient absorption measurements showed that the expected reduced one-electron intermediate, RuCP⁺, was formed on a sub-nanosecond time scale with back electron transfer to the electrode on the microsecond timescale which competes with forward electron transfer to the Re(I) catalyst at t₁/₂ = 2.6 μs (kₑT = 2.7 × 10⁵ s⁻¹).

Introduction

In natural photosynthesis, conversion of sunlight and CO₂ into chemical fuels integrates light absorption and catalysis.† In Dye Sensitized Photocatalysis Cells (DSPECs) molecular assemblies are integrated with light absorbers and catalysts on electrode surfaces for water splitting or reduction of CO₂.⁸–¹² Significant advances have been made in the last ten years developing high efficiency photoanodes for water oxidation and proton reduction, while progress on the development of high photocurrent efficiency photocathodes for CO₂ reduction still remains challenging.¹³–¹⁸

Due to its chemical significance, many innovative approaches have been developed to advance the photoreduction of CO₂.²²–³¹ These studies reflect considerable effort to use abundant minerals as catalysts and light absorbers alongside the long standing issue of developing more efficient components as a whole. Several novel strategies have been utilized for CO₂ fixation including biosynthesis,²₇ the use of spongy materials,²₈ and utilization of metal–organic-frameworks.³¹

The approach to CO₂ reduction using a DSPEC in this work makes use of molecular chromophore and catalyst species adsorbed on a NiO semiconductor electrode. Using this strategy, Ishitani and co-workers have made significant progress in the area of CO₂ reduction devices,³³,³⁴ and related approaches between these and water splitting photoanodes such as the use of tandem cells for unbiased DSPEC operation and development of more effective photocathode materials have been advanced in recent years.³⁵,³⁶

The key reactions involved in the light-driven CO₂ reduction process for this device are summarized in eqn (1)–(3). Excitation of the chromophore (Chrom) by sunlight in eqn (1), results in an excited state which, following excitation and injection, leads to formation of a hole in the semiconductor NiO(h⁺), and electron transfer to the catalyst, Cat, eqn (2). The latter begins the process of catalyst activation of a cycle for CO₂ reduction, eqn (3). The latter reaction is in competition with back electron transfer from the electrode in this device, eqn (4). The final step in the process, to complete the circuit, is conduction of the injected hole to an anode (here, a Pt wire for dark water oxidation), eqn (5).

Injection

\[ \text{NiO(Chrom-Cat} + h\nu \rightarrow \text{NiO(h}^+)\text{Chrom(e}^-)\text{-Cat} \] (1)

Catalyst activation

\[ \text{NiO(h}^+)\text{Chrom(e}^-)\text{-Cat} \rightarrow \text{NiO(h}^+)\text{Chrom-Cat(e}^-) \] (2)

CO₂ reduction step

\[ \text{NiO(h}^+)\text{Chrom-Cat(e}^-) + \text{CO}_2 \rightarrow \text{NiO(h}^+)\text{Chrom-[Cat-CO}_2^- \] (3)

Back electron transfer

\[ \text{NiO(h}^+)\text{Chrom-Cat(e}^-) \rightarrow \text{NiO}[\text{Chrom-Cat} \] (4)

Anode oxidation

\[ \text{NiO(h}^+)\text{Chrom-[Cat-CO}_2^- + \text{anode} \rightarrow \text{NiO}[\text{Chrom-Cat(e}^-] + \text{anode(h}^+) \] (5)

However, the collective results of an extensive literature on NiO based photocathodes have not been promising for practical applications thus far. Transient optical experiments have shown that, following excited state injection on NiO, rapid back electron transfer dominates (eqn (4)), resulting in low steady state concentrations of semiconductor holes and low photocurrent efficiencies in the multi-electron reduction of CO₂ to CO, eqn (6).

\[ 2\text{H}^+ + \text{CO}_2 + 2\text{e}^- \rightarrow \text{H}_2\text{O} + \text{CO} \] (6)

In natural photosynthesis, photon excitation and electron transfer catalysis are linked through a network of redox active groups that provide a free energy gradient for directed electron and hole transfer. This natural assembly supports electron transfer over long distances which inhibit back electron transfer because of the exponential dependence of outer-sphere electron transfer on distance. The strategy has not been generally utilized, in part, because of the complexity of adding additional components to the device and a lack of understanding various pathways for electron transfer.

We report here a layer-by-layer preparation and the resulting properties of a chromophore-catalyst assembly for CO₂ reduction to CO. The approach also provides spatial control of electron transfer by using an electron-donating dianiline mediator (‘Donor’). The assembly was based on a previous report of assembly formation by layer-by-layer synthesis that gave assemblies integrated functional units for light absorption, electron transfer quenching, and catalysis in single molecule arrays. Here, the same procedure was utilized to prepare a NiO|donor-chromophore-catalyst molecular assembly for CO₂ reduction in a DSPEC. The complete surface assembly produced sustained photocurrents (>45 \(\mu\)A cm\(^{-2}\) over 20 minutes), and produced CO with a faradaic efficiency of 85% under an applied bias of −0.54 V vs. NHE.

**Experimental**

**Materials**

Dry acetonitrile was purchased from Sigma-Aldrich and used as received. All other reagents were purchased from Sigma-Aldrich without further purification. N\(_4\)N\(_4\)'N\(_4\)'-[(CH\(_3\))\(_2\)PO\(_2\)H\(_2\)]4,4'-dianiline (DA) was prepared according to the reported literature. The [Ru(4,4'-{(PO\(_2\)H\(_2\)CH\(_2\)_2}2-2,2'-bipyridine)]\(_{2}\)\(_2\) (RuCP\(_2\)^{2+}\) chromophore was made according to previously published procedures. The Re complex was prepared following the protocol reported by Schreier et al.

**Film preparation**

**NanoITO**. nanoITO films were prepared by using the doctor blade method. In detail, the nanoITO paste was prepared by mixing 0.5 g hydroxypropyl cellulose (MW 100 000) into 30% ITO ethanol solution. A mixture was stirred until the solution turned clear and allowed to sit for 48 hours, followed by centrifugation at 3000 rpm for 15 min. Following centrifugation the supernatant liquid was doctor-bladed on a thoroughly cleaned FTO glass slides. After drying in air, the slide as were placed in a box oven for 1 hour at 450 °C. The film thickness was estimated as ca. 2.3 μm by profilometry.

**NiO mesoporous films**. 1.0 g NiCl\(_2\)-6H\(_2\)O was dissolved in 3 mL water, then 1.0 g co-polymer F-108 (Sigma) was added followed by the addition of 6.0 g of ethanol to the mixture. The mixture was stirred until the solution turned clear and allowed to sit for 48 hours, followed by centrifugation at 3000 rpm for 15 min. Following centrifugation the supernatant liquid was doctor-bladed on a thoroughly cleaned FTO glass slides. After drying in air, the slide as were placed in a box oven for 30 min at 120 °C, and heated to 450 °C for 30 min. This process was repeated twice to get ca. 1.0 μm thick films.

**Surface assembly formation**

NiO films were first immersed in 0.1 M HClO\(_4\) aqueous solutions containing 2 mM of the aromatic donor N\(_4\)N\(_4\)'N\(_4\)'-[(CH\(_3\))\(_2\)PO\(_2\)H\(_2\)]4,4'-dianiline (DA) for 12 hours. After copious rinsing with 0.1 M HClO\(_4\) water, they were dried under N\(_2\) and placed in a 5 mM aqueous solution of zirconyl chloride (ZrOCl\(_2\)) with 0.1 M HClO\(_4\) for 2 hours. Following a drying cycle under N\(_2\), the thin films were further immersed in a 0.1 mM solution of the chromophore [Ru(4,4'-{(PO\(_2\)H\(_2\)CH\(_2\)_2}2-2,2'-bipyridine)]\(_{2}\)\(_2\) (RuCP\(_2\)^{2+}\) for 12 hours. Surface coordination was followed by rinsing and drying steps and then addition of a second layer of Zr(v).

In the final step, the NiO|DA-Zr(v)-RuCP\(_2\)^{2+}-Zr(v) electrodes were soaked in methanol solutions containing the catalyst, Re\(_4\)'(4,4'-{(PO\(_2\)H\(_2\)CH\(_2\)_2}2-2,2'-bipyridine)(CO)\(_2\)Cl, at 2 mM for 24 hours to give the assembly, NiO|DA-RuCP\(_2\)^{2+}-Re(v).

The control electrode NiO|RuCP\(_2\)^{2+}-Re(i) was fabricated by immersing NiO films in a 0.1 mM solution of the chromophore [Ru(4,4'-{(PO\(_2\)H\(_2\)CH\(_2\)_2}2-2,2'-bipyridine)]\(_{2}\)\(_2\)\(_2\) (RuCP\(_2\)^{2+}\) for 12 hours. Surface coordination was followed by rinsing and drying steps and then addition of a layer of Zr(v) which was formed by soaking in a 5 mM aqueous solution of ZrOCl\(_2\) in 0.1 M HClO\(_4\) for 2 hours. In the next step, the NiO|RuCP\(_2\)^{2+}-Zr(v) electrodes were soaked in methanol solution.
containing the catalyst, \( \text{Re}^{0}((4,4^{'-}\text{PO}_{3}\text{H}_{2}\text{CH}_{2})_{2}-2,2^{'-}\text{bipyridine})(\text{CO})_{3}\text{Cl} \) at 2 mM for 24 hours to give the assembly, \( \text{NiO}|-\text{RuCP}_{2}^{2+}-\text{Re}^{0} \). The electrode nanoITO|-RuCP\(_{2}^{2+}\)-Re(i) was made using an identical procedure but with nanoITO replacing the NiO film.

**Instrumentation**

UV-visible absorbance measurements were performed using an Agilent Technologies Cary 8454 UV-visible spectrometer.

Scanning electron microscope (SEM) images were obtained on a FEI Helios 600 Nanolab Dual Beam System focused ion beam (FIB) equipped with an Oxford Instruments, INCA PentaFET-x3 X-ray detector with the electron beam set to 2 keV and a beam current of 0.69 nA.

XPS spectra were acquired by using a Kratos Axis Ultra DLD X-ray photoelectron spectrometer with a base pressure of \( 6 \times 10^{-9} \text{ Torr} \), a monochromatic Al K\( \alpha \) X-ray source, and an analyzer pass energy of either 80 eV or 20 eV for survey and high resolution scans respectively.

X-ray diffraction were used to characterize the prepared NiO films. A Rigaku SmartLab was utilized which consisted of an X-ray source (3 kW Cu tube) and the detector – a 0D scintillation detector.

**Gas chromatography**

At the end of a photoelectrochemical experiment, 0.6 mL of a gaseous sample was taken out of the sealed headspace by a gas tight syringe (Vici) and injected into a gas chromatograph (Varian). A gaseous sample was taken out of the sealed headspace by a gas detector. A CH Instruments 660D potentiostat was used to record the photocurrent transients and a bias of 260 monochromator. Photocurrent data were taken at 5 nm increments and the light intensity at each wavelength was formed with a 75 W xenon lamp (Oriel) and Oriel Cornerstone photon to current e\( _{ff} \) provided by a THORLABS HPLS 30-04 light source. Incident upon the NiO film.

**Results and discussion**

**Synthesis and characterization**

Scheme 1 illustrates the components used for the preparation of the surface assembly. Coordination to the surface and assembly formation were based on phosphonate–Zr(IV) bridges on the surfaces of mesoporous 1.0 \( \mu \)m thick films of NiO composed of 15–20 nm diameter NiO particles.38–39 SEM and XRD characterization of NiO films are shown in Fig. S1 and S2.† Details on the preparation of the NiO films is provided in the experimental section. The final structure, with the Zr(IV) bridging groups, is shown in Scheme 1, with a redox potential diagram shown in Fig. 1.

UV-visible absorption measurements were used to monitor assembly formation. Typical data are illustrated in Fig. 2 for NiO|-DA, NiO|-DA-RuCP\(_{2}^{2+}\) and NiO|-DA-RuCP\(_{2}^{2+}\)-Re(i). The spectrum of the assembly NiO|-DA-RuCP\(_{2}^{2+}\)-Re(i) includes a metal-to-ligand charge-transfer (MLCT) absorption maximum at 460 nm which corresponds to a region expected for the Ru(n) chromophore MLCT. In the final assembly, NiO|-DA-RuCP\(_{2}^{2+}\)-Re(i), the absorption spectrum includes an additional feature, the CO\(_{2}\) catalyst, with a MLCT absorption at 350–450 nm. The spectrum...
The redox potential diagram for the assembly, NiO|-DA-RuCP₂²⁺-Re(I), illustrating excitation and stepwise electron transfer following excitation of the RuCP₂²⁺ chromophore.

Fig. 1 UV-visible absorption spectra of neutral molecular assemblies on NiO electrodes measured in air (top), and the corresponding spectra for each oxidized (DA) or reduced (RuCP₂ or Cat) species obtained by spectroelectrochemistry (bottom).

The photocurrent responses of NiO|-RuCP₂²⁺-Re(i) and NiO|-DA-RuCP₂²⁺-Re(i) electrodes were studied using a standard three-electrode photoelectrochemical cell with 1 sun illumination (100 mW cm⁻², 400 nm cutoff filter) in CO₂ saturated 0.1 M LiClO₄ acetonitrile solution. The working electrodes were NiO|-
RuCP$_2$$^{2+}$-Re(i) or NiO|-DA-RuCP$_2$$^{2+}$-Re(i) with a platinum wire as the counter electrode and a Ag/Ag$^+$ quasi-reference electrode. After three 10 s light on/off cycles, the photocurrent response for NiO|-DA-RuCP$_2$$^{2+}$-Re(i) was ~65 $\mu$A cm$^{-2}$ at the end of each cycle. This photocurrent response was nearly 8 times larger than that measured for an assembly without the DA electron transfer mediator, NiO|-RuCP$_2$$^{2+}$-Re(i), as shown in Fig. 3a. The enhanced photocurrent density with the dianiline donor arises from intra-assembly electron transfer initially from the DA donor to the MLCT excited state of RuCP$_2$$^{2+}$*, discussed below. Results of a long term photolysis experiment using NiO|-DA-RuCP$_2$$^{2+}$-Re(i) conducted over a 20 min period (Fig. 3b) showed photocurrents for the assembly NiO|-DA-RuCP$_2$$^{2+}$-Re(i) decreasing by ca. 40% over this time period.

To test for the effect of applied bias, current densities were measured with the bias voltage was scanned from $-0.95$ to $0.4$ V vs. NHE under light and dark conditions, Fig. S8.$^\dagger$ More negative applied voltages increased the photocurrent density up to the background catalytic wave starting at ca. $-0.8$ V. As a note, there was no evidence for background catalytic behavior toward CO$_2$ reduction by NiO|-DA-RuCP$_2$$^{2+}$-Re(i) until an applied bias of $-0.8$ V vs. NHE was reached under dark conditions. When illuminated, the NiO|-DA-RuCP$_2$$^{2+}$-Re(i) photocathode maintained in cathodic current up to a bias of $-0.1$ V vs. NHE, $0.7$ V more positive than the electrocatalytic onset potential. For comparison, the same experiments were carried out with the assembly NiO|-RuCP$_2$$^{2+}$-Re(i) under dark and light conditions in CO$_2$ saturated 0.1 M NaClO$_4$ acetonitrile solution as shown in Fig. S9.$^\dagger$ While the surface still showed a photocathodic response, the photocurrent density was substantially lower as compared to the full assembly containing the DA unit (Fig. S8$^\dagger$), consistent with Fig. 3a. As noted above, the photocurrent density obtained at the DA assembly represents significant improvement over the electrode without the electron mediator, NiO|-RuCP$_2$$^{2+}$-Re(i). Enhancements in the photocurrent can be largely attributed to better local charge separation and reduced back electron transfer with the added dianiline donor.

Incident photon-to-current efficiency (IPCE) measurements as a function of excitation wavelength are shown in Fig. S10.$^\dagger$ The IPCE value for the assembly NiO|-DA-RuCP$_2$$^{2+}$-Re(i) was obtained at an applied bias of $-0.54$ V versus NHE in CO$_2$ saturated 0.1 M NaClO$_4$ acetonitrile solution. The IPCE profiles overlap with the MLCT absorption profile for the chromophore, as expected for dye-sensitized CO$_2$ reduction. From Fig. S10,$^\dagger$ the IPCE value for the assembly, NiO|-DA-RuCP$_2$$^{2+}$-Re(i), was 1.9% at the absorption maximum for the RuCP$_2$$^{2+}$ chromophore at 450 nm.

**Product analysis**

Gas chromatography (GC) was used to estimate faradaic efficiencies for CO$_2$ reduction to CO for both NiO|-RuCP$_2$$^{2+}$-Re(i) and NiO|-DA-RuCP$_2$$^{2+}$-Re(i). GC analysis revealed that CO was the major product for both assemblies as shown in Fig. 4. From the data in Fig. 4, the appearance of CO for NiO|-DA-RuCP$_2$$^{2+}$-Re(i), as a product of CO$_2$ reduction, is considerably enhanced compared to NiO|-RuCP$_2$$^{2+}$-Re(i). For the latter, the ratio of H$_2$ to CO was 1 : 3 and for the former (assembly with DA), the ratio of H$_2$ to CO was 1 : 8.

The product distribution for NiO|-DA-RuCP$_2$$^{2+}$-Re(i) was also investigated as a function of applied potential. At $-0.54$ V NHE, the ratio of CO to H$_2$ increased nearly to 30 : 1 with concurrent increase in the faradaic efficiency for CO production to 85% with 3% H$_2$ production. The turnover number (TON) for CO$_2$ reduction from this experiment was calculated by comparing it to the number of adsorbed catalyst species and a TON of 22 was obtained with a bias of $-0.54$ V vs. NHE during 20 min measurements. By further increasing or decreasing the bias from $-0.54$ V, CO production was decreased.

**Transient absorption**

Interfacial, light-induced electron transfer dynamics were investigated by nanosecond transient absorption measurements...
on NiO|-DA-RuCP2\(^{2+}\)\(\text{-Re(I)}\) and NiO|-DA-RuCP2\(^{2+}\). Samples were excited with pulsed 488 nm excitation (4.5 mJ per pulse) in argon-saturated 0.1 M LiClO\(_4\) acetonitrile solutions with an applied bias of \(-0.8\) V vs. NHE. As shown in Fig. 5, transient absorption difference spectra measured after pulsed laser excitation revealed the prompt appearance of a band near 520 nm and an absorption edge that increased into the UV region.

For NiO|-DA-RuCP2\(^{2+}\), excitation of the chromophore results in rapid \((k > 10^{8} \text{ s}^{-1})\) intra-assembly quenching to give NiO|-DA\(^{+}\)-RuCP2\(^{2+}\), eqn (7), and, subsequent electron transfer to NiO(h\(^{-}\))-DA-RuCP2\(^{2+}\) (eqn (8)) after hole injection into NiO. The overall conversion to the final surface-assembly-based redox state is summarized in eqn (8), with back electron transfer a competing reaction, eqn (9). The initial electron transfer quenching by the diaminine, eqn (7), is favored by 0.19 V, and is not observed experimentally. Based on these results, and the 20 ns instrument response time, the rate constants for both the electron transfer from DA to RuCP2\(^{2+}\) and from NiO to DA\(^{+}\) are assumed to be \(>10^{8} \text{ s}^{-1}\).

As shown by the data in Fig. 6, extension of the transient absorption measurements to NiO|-DA-RuCP2\(^{2+}\)-Re\((\text{i})\) gave comparable results. Analysis of time-dependent data at 530 nm showed that the kinetics of back electron transfer were non-exponential for both assemblies. The kinetics were characterized by the half time for the distribution, \(t_{1/2}\), the time at which the signal has decreased to half of its original amplitude. For the traces shown in Fig. 6, with the Re\((\text{i})\) catalyst, NiO(h\(^{-}\))-DA-
This article is licensed under a Creative Commons Attribution-NonCommercial 3.0 Unported Licence.

Insight into the mechanism for CO2 reduction to CO from the structures to give the electrode, NiO|-DA-RuCP2 +, t1/2 was 8.3 μs. It is notable that the lifetime for the NiO(h +)|-DA-RuCP2 + precursor decreased by a factor of ca. 4 compared to NiO(h +)|-DA-RuCP2 +. This is consistent with electron transfer from RuCP2 + to Re(i), eqn (11).

Next, to calculate the kinetic rate constant for electron transfer in eqn (11), the difference in the loss of RuCP2 signal in the catalyst assembly can be attributed to either back electron transfer to NiO(h +) or electron transfer to the catalyst. Assuming the rate of back electron transfer is unchanged in the catalyst assembly, the equation for the rate constant is $k_{eqn(11)} = 2/(t_{1/2, A} + 1/t_{1/2, B})$, where $t_{1/2, A}$ and $t_{1/2, B}$ are the two $t_{1/2}$ obtained thus far. The calculated rate constant for eqn (11), $k_{eqn(11)}$ or $k_{CT}$, is therefore $3.7 \times 10^5$ s$^{-1}$ ($t_{1/2, eqn (11)} = 2.6$ μs). In comparison, Zr(IV) assemblies for light-driven water oxidation, hole transfer occurs with a half-life of 170 ps or 0.00017 μs ($k_{CT} = 5.9 \times 10^5$ s$^{-1}$). The order of magnitude more sluggish electron transfer behaviour for transfer to the Re(i) catalyst is attributable to the 0.01 eV driving force for the reaction in eqn (11).

$$\text{NiO-DA-RuCP}^2_2^-\text{Re(t)} \rightarrow \text{NiO-DA-RuCP}^2_2^-\text{Re(0)} \quad (11)$$

**Mechanism**

Insight into the mechanism for CO2 reduction to CO from the transient absorption experiments is limited by back electron transfer to the electrode. On the timescale of the nanosecond experiments, there is significant kinetic competition between back electron transfer and the rate of activation of the Re(i) catalyst without additional insight into the mechanism of CO2 reduction.

There is an extensive mechanistic background in this area based on previous studies of Re(i) catalyst analogs in solution and as a component in assemblies with Ru(n) polypyridyl complexes. Eqn (12) and (13) summarize the initial mechanistic steps. In the overall mechanism, the catalytic cycle is initiated by visible light absorption by the MLCT chromophore, -RuCP2 +, to give the MLCT excited state, -RuCP2 +. Formation of the excited state is followed by its reduction by electron transfer from -DA- and electron transfer from the electrode to DA to give -RuCP2 + and NiO(h +). As shown in eqn (13), further electron transfer from the reduced chromophore occurs to the catalyst on the sub-ms timescale.

$$\text{NiO-DA-RuCP}^2_2^-\text{Re(t)} + h\nu \rightarrow \text{NiO(h +)}|\text{DA-RuCP}^2_2^-\text{Re(t)} \quad (12)$$

$$\text{NiO(h +)}|\text{DA-RuCP}^2_2^-\text{Re(t)} \rightarrow \text{NiO-DA-RuCP}^2_2^-\text{Re(0)} \quad (13)$$

**Conclusions**

We have successfully demonstrated here the synthesis, characterization, and properties of a surface-bound assembly for CO2 reduction to CO on the surface of mesoporous NiO electrodes. Formation of the electrode followed from a stepwise assembly synthesis based on phosphonate-Zr(IV) bridged structures to give the electrode, NiO|-DA-RuCP2 +. Compared to the assembly, NiO|-RuCP2 +, addition of the DA-aniline donor was found to accelerate the catalytic effect by a factor of 8 by initial reduction of the MLCT excited state, -RuCP2 +, by the dianiline electron-donating mediator. With 1 sun illumination, photocurrents of up to 65 μA cm$^{-2}$ were obtained for NiO|-DA-RuCP2 + for CO2 reduction to CO under an atmosphere of CO2 in acetonitrile as the solvent.

Nanosecond transient absorption measurements have been used to show that, in the assembly, initial excitation of the chromophore is followed by rapid, electron transfer to gives intermediate, NiO(h +)|-DA-RuCP2 +. This state undergoes back electron transfer on timescales shorter than a millisecond. Although not directly observed in the transient experiments, with an applied bias, reduction of the catalyst appears to be followed by a sequence of reactions that activate the catalyst toward CO2 reduction. Collectively the data show that a layer-by-layer synthetic approach can be utilized to spatially organize electron donors, catalysts, and chromophores on NiO surfaces for applications in solar fuel production.
