DRIVERS AND MECHANISMS OF PEAT COLLAPSE IN COASTAL WETLANDS

A dissertation submitted in partial fulfillment of

the requirements for the degree of

DOCTOR OF PHILOSOPHY

in

BIOLOGY

by

Benjamin J. Wilson

2018

To: Dean Michael R. Heithaus
College of Arts, Sciences and Education

This dissertation, written by Benjamin J. Wilson, and entitled Drivers and Mechanisms of Peat Collapse in Coastal Wetlands, having been approved in respect to style and intellectual content, is referred to you for judgment.

We have read this dissertation and recommend that it be approved.

John Kominoski

Steven Oberbauer

Leonard Scinto

Jennifer Richards, Co-Major Professor

Tiffany Troxler, Co-Major Professor

Date of Defense: March 23, 2018

The dissertation of Benjamin J. Wilson is approved.

Dean Michael R. Heithaus
College of Arts, Sciences and Education

Andrés G. Gil
Vice President for Research and Economic Development
and Dean of the University Graduate School

ACKNOWLEDGMENTS

It's been a long journey, and there are many people to thank who helped me get to this point. I would like to first and foremost thank my two wonderful advisors, Dr. Tiffany Troxler and Dr. Jennifer Richards, for taking a chance on me and allowing me the freedom to craft my research. Their constant guidance and feedback helped develop not only this dissertation but my character as well. I want to especially thank one member of my committee, Dr. John Kominoski. John took me into his lab from day one and has contributed immensely to my growth as a scientist. Long discussions with John and constant feedback from him accelerated the advancement of my work. I would also like to thank the members of my committee: Dr. Steve Oberbauer and Dr. Len Scinto. Without their helpful comments on my project and use of their instruments, I would not have been able to complete my dissertation. A one last special shout out to my unofficial committee member, Dr. Evelyn Gaiser. Evelyn's constant positivity and insights guided so much of my research and decisions.

There are a few graduate students who I have been working closely with during my time at FIU: Sean Charles, Viviana Mazzei, Nick Schulte, and Shelby Servais. We all started at the same time and have been providing each other with project guidance, emotional support, and an ear to voice endless rants. It is their motivation that has kept me going. Long conversations in the lab had led to many new research insights.

The research I conducted was part of a very large collaborative effort among many organizations, and it would be impossible for me to not thank them. I want to thank Dr. Steve Davis at the Everglades Foundation; Dr. Fred Sklar, Dr. Carlos Coronado, Steve Kelly, and Joe Stachelek at the South Florida Water Management District; and Dr.

Dave Rudnick at Everglades National Park. Through monthly strategy calls, many in-person meetings, lots of long field days, and written feedback, these people provided the framework to get this research done.

I want to thank all the help I've received in both the lab and the field from the Troxler lab: Shawn Abrahams, Laura Bauman, Dr. Edward Castaneda, Marbelys Garriga, Adam Hines, Rowan Johnson, Oliver Ljustina, Melinda Martinez, Chris Sullivan, Emily Standen, Ryan Stolee, Geoff Szafranski, and Mary Grace Thibault. You guys are the underappreciated workhorses that get research done!

I want to thank all of the other graduate students and friends that I met along the way. Our chats over beers, on the beach, and around the BBQ helped me stay sane enough to finish: Josh Allen, Claire Burgett, Dr. Ross Boucek, Dr. Mike Bush, Dr. Justin Cummings, Belén Fadrique, Carissa Gervasi, Brittany Harris, Greg Hill, Jason Howard, Lukas Lamb-Wotton, Cristina Lebròn, Dr. Dong Yoon Lee, Luke Linhoff, Chris Lopes, Ximena Mesa, Nico Sebesta, Matt Smith, James Stroud, Dr. Kristie Wendelberger, and Daniel Virden.

Funding for this research came from many sources. The majority of this work was supported by Florida Sea Grant R/C-S-56 and the Florida Coastal Everglades Long Term Ecological Research Program (NSF DEB-1237517). Support for chapter IV came from the National Science Foundation Doctoral Dissertation Improvement Grant (DEB-1701763). I was funded by a Florida International University Graduate Teaching Assistantship, FIU Dissertation Year Fellowship, and on research assistantships through the Florida Sea Grant and FCE LTER.

Finally, I would like to thank my family for all the love and nurturing they have given me to reach this point. Special shout out to my Mom's care packages. Thanks Michele, Scott, Nick, Jon, and Sophie.

ABSTRACT OF THE DISSERTATION
DRIVERS AND MECHANISMS OF PEAT COLLAPSE IN COASTAL WETLANDS

by

Benjamin J. Wilson

Florida International University, 2018

Professor Jennifer Richards, co-Major Professor

Professor Tiffany Troxler, co-Major Professor

Coastal wetlands store immense amounts of carbon (C) in vegetation and sediments, but this store of C is under threat from climate change. Accelerated sea level rise (SLR), which leads to saltwater intrusion, and more frequent periods of droughts will both impact biogeochemical cycling in wetlands. Coastal peat marshes are especially susceptible to saltwater intrusion and changes in water depth, but little is known about how exposure to salinity affects organic matter accumulation and peat stability. I investigated freshwater and brackish marsh responses to elevated salinity, greater inundation, drought, and increased nutrient loading. Elevated salinity pulses in a brackish marsh increased CO₂ release from the marsh but only during dry-down. Elevated salinity increased root mortality at both a freshwater and brackish marsh. Under continuously elevated salinity in mesocosms, net ecosystem productivity (NEP) was unaffected by elevated salinity in a freshwater marsh exposed to brackish conditions (0 → 8 ppt), but NEP significantly increased with P enrichment. Elevated salinity led to a higher turnover of live to dead roots, resulting in a ~2-cm loss in soil elevation within 1 year of exposure to elevated salinity. When exposing a brackish marsh to more saline conditions (10 → 20

ppt), NEP, aboveground biomass production, and root growth all significantly decreased with elevated salinity, shifting the marsh from a net C sink to a net C source to the atmosphere. Elevated salinity (10 → 20 ppt) did not increase soil elevation loss, which was already occurring under brackish conditions, but when coupled with a drought event, elevation loss doubled. My findings suggest these hypotheses for the drivers and mechanisms of peat collapse. When freshwater marshes are first exposed to elevated salinity, soil structure and integrity are negatively affected through loss of live roots within the soil profile, leaving the peat vulnerable to collapse even though aboveground productivity and NEP may be unaffected. Subsequent dry-down events where water falls below the soil surface further accelerate peat collapse. Although saltwater intrusion into freshwater wetlands may initially stimulate primary productivity through a P subsidy, the impact of elevated salinity on root and soil structure has a greater deleterious effect and may ultimately be the factors that lead to the collapse of these marshes.

LIST OF TABLES

TABLE		PAGE
CHAPTER I		
1	Soil physicochemical properties (mean $\pm$ SE, n = 6) by site and by depth.....	56
2	Full statistical results from a linear mixed model for porewater constituents from the freshwater (FW) and brackish water (BW) sites given treatment (trt) and date. Interpreted results in bold. Data presented as F(numerator degrees of freedom,denominator degrees of freedom) = F value, P = P value. The arrows indicate, if significant, in what direction elevated salinity altered the given parameter. DOC dissolved organic carbon, NH_4^+ ammonium, TDN total dissolved nitrogen, SO_4^{2-} sulfate, TDP total dissolved phosphorus, SRP soluble reactive phosphorus.....	57
3	Mean $\pm$ SE of C, N, and P sawgrass leaf content for each year. Subscripted letters represent differences between year and treatment within a site from a one-way ANOVA.....	58
4	Full statistical results from a linear mixed model for all biomass and flux measurements. Interpreted results in bold. Data presented as F(numerator degrees of freedom,denominator degrees of freedom) = F value, P = P value. ANPP aboveground net primary productivity, GEP gross ecosystem productivity, ER_{CO_2} ecosystem respiration of carbon dioxide, NEP net ecosystem productivity, CH_4 methane.....	59
5	Belowground live root biomass (mean $\pm$ SE g C m^{-2}) after two years of control (+AMB) and elevated salinity (+SALT) from each site, each treatment and from specific depths. A two-way ANOVA was run separately for each site with Treatment and Depth as factors. Total depth was compared for each site separately using an independent t-test. Letters indicates a significant difference ($P < 0.10$).....	60
6	Mean $\pm$ SE of net ecosystem productivity (NEP), gross ecosystem productivity (GEP), ecosystem respiration of CO_2 (ER_{CO_2}), and ecosystem respiration of CH_4 (ER_{CH_4}) from the brackish water (BW) and freshwater (FW) sites, separated by the “no-chamber” control, addition of ambient water (+AMB), and the addition of saltwater (+SALT) plots. Fluxes were separated into wet (water covering the soil surface) and dry (no surface water) periods. A negative NEP indicates a flux from the marsh to the atmosphere. Subscripts represent the results of a two-way repeated measures ANOVA. Values without superscripts	

indicates that there was no significant difference between treatments for that parameter.....61

CHAPTER II

- 1 Porewater temperature, salinity, pH, and dissolved constituents. Data represent mean ($n=6$ replicates) ± 1 standard error of temperature, salinity, pH, and dissolved porewater constituents averaged across treatments. DOC, NO_2^- , NO_3^- , NH_4^+ , and SRP are in $\mu\text{mol L}^{-1}$, HS^- is in mM. Letters represent significant differences among treatments from a multiple comparison test (LSMEANS, Tukey adjusted). DOC dissolved organic carbon, NO_2^- nitrate, NO_3^- nitrite, NH_4^+ ammonium, SRP soluble reactive phosphorus.....102
- 2 Full statistical results for the linear mixed model. Model run with time as an independent variable for temperature, salinity, pH, dissolved porewater constituents, ecosystem C flux, biomass, and redox. Interpreted results are in bold. Data presented as F(numerator degrees of freedom, denominator degrees of freedom) = F value, P = P value. DOC, TOC, NO_2^- , NO_3^- , NH_4^+ , and SRP are in $\mu\text{mol L}^{-1}$. Interpreted results are in bold. DOC dissolved organic carbon, NH_4^+ ammonium, TDN total dissolved nitrogen, SO_4^{2-} sulfate, TDP total dissolved phosphorus, SRP soluble reactive phosphorus, GEP gross ecosystem productivity, ER_{CO_2} ecosystem respiration of CO_2 , NEP net ecosystem productivity, ANPP aboveground net primary productivity.....103
- 3 Averaged carbon flux measured over the experimental period. Data represent the mean ($n=4$ or 6) ± 1 SE of net ecosystem productivity (NEP), gross ecosystem productivity (GEP), ecosystem respiration of CO_2 (ER_{CO_2}), soil CO_2 (all in $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$), and soil CH_4 flux ($\text{nmol CH}_4 \text{ m}^{-2} \text{ s}^{-1}$) from each treatment over the duration of the experiment. Letters represent significant differences among treatments from a multiple comparison test (LSMEANS, Tukey adjusted).....105
- 4 Calculated sustained-flux global warming potential (SGWP) over a 100-year period and corrected net ecosystem productivity (NEP) accounting for the contribution of methane (CH_4) to the global greenhouse carbon balance. All units are in $\text{mg C m}^{-2} \text{ min}^{-1}$. SGWP is calculated as 45 times the measured soil CH_4 flux when CH_4 was emitted, and as 203 times soil CH_4 flux when there was uptake (Salt) (Neubauer and Megonigal 2015). Corrected NEP is calculated as the difference between NEP and SGWP....106

CHAPTER III

- 1 Porewater salinity, pH, redox, and dissolved constituents for the soil-only experiment. Data represents mean ± 1 SE ($n=6$ replicates); see linear mixed model results (Table S2) for significant differences

between the two experiments. DOC, NH_4^+ , TDN, and SO_4^{2-} are in mg L^{-1} , HS^- is in mM, TDP and SRP are μM , and redox potential is in mV. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....152

- 2 Full statistical results for the linear mixed model run with time as an independent variable for C flux and aboveground net primary productivity (ANPP). Results with $\alpha < 0.05$ are in bold. Data presented as F(numerator degrees of freedom, denominator degrees of freedom) = F value, P = P value. GEP gross ecosystem productivity, ER_{CO_2} ecosystem respiration of CO_2 , NEP net ecosystem productivity.....153
- 3 Flux rates from the plant-soil experiment. Values represent the mean ($\mu\text{mol CO}_2$ or $\text{CH}_4 \text{ m}^{-2} \text{ s}^{-1}$) ± 1 SE for soil CO_2 (n=90), soil CH_4 (n=36), gross ecosystem productivity (GEP), ecosystem respiration of CO_2 (ER_{CO_2}), and net ecosystem productivity (NEP; n=52) compared over the entire experiment for each treatment for the plant-soil experiment. See mixed model results (Table 2) for significant differences. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....154
- 4 Coefficient of determination for linear relationships between *Cladium jamaicense* aboveground biomass and ecosystem CO_2 exchange [gross ecosystem productivity (GEP), net ecosystem productivity (NEP), and ecosystem respiration (ER_{CO_2})]. ns = non-significant ($p > 0.05$), * $p \leq 0.05$, ** $p < 0.01$. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....155
- 5 Soil CO_2 and CH_4 efflux compared across similar periods and treatments for each experiment. Values represent the mean ($\mu\text{mol CO}_2$ or $\text{CH}_4 \text{ m}^{-2} \text{ s}^{-1}$) ± 1 SE. See mixed model results for significant differences between treatments (Table 2) and experiments (Table S3). Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....156

CHAPTER IV

1	Net ecosystem carbon balance of a brackish water marsh. Mean $\pm$ 1 SE of the net annual ecosystem carbon (C) balance ($\text{g C m}^{-2} \text{ yr}^{-1}$) for a brackish water marsh. A positive number indicates an input of C to the marsh, while a negative number indicates a net output of C from the marsh. Statistical information regarding the influence of elevated salinity, drought, and their combined effects can be found in Table S2. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed. n=4 for NEP, GEP, ERCO ₂ ; n=6 for Soil CO ₂ , ANPP, Root ingrowth, Root Decomp, and Leaf Decomp. NEP net ecosystem productivity, GEP gross ecosystem productivity, ERCO ₂ ecosystem respiration of CO ₂ , ANPP aboveground net primary productivity, Decomp decomposition.....	175
---	--	-----

LIST OF FIGURES

FIGURES		PAGE
CHAPTER I		
1	Experimental setup at the FW site (not to scale). The setup was similar at the BW site. Sixteen plots were established along a boardwalk, with a 3-m buffer zone between the saltwater-amended plots and the ambient water-amended plots. “No-chamber” controls received no water additions. The +SALT plots were positioned downstream of flow to minimize contamination of the control plots.....	47
2	Mean ($n=6$) $\pm$ 1 SE of monthly porewater temperature, salinity, pH, alkalinity, sulfate (SO_4^{2-}), dissolved organic carbon (DOC), ammonium (NH_4^+), total dissolved nitrogen (TDN), soluble reactive phosphorus (SRP), and total dissolved phosphorus (TDP) from the freshwater (FW) and brackish water (BW) sites over the two-year duration of the study taken at 15-cm depth from the ambient water (+AMB) and saltwater (+SALT) addition plots. Salinity is reported as parts per thousand, Alkalinity, SO_4^{2-} , DOC, NH_4^+ , and TDN are reported in mg L^{-1} , and SRP and TDP are reported in $\mu\text{g L}^{-1}$	49
3	Mean ($n=6$) $\pm$ 1 SE of monthly porewater (PW) and surface water (SW) salinity and daily water depth from the brackish water site within the +ambient-water plots. Soil surface is plotted as the 0-cm water mark (dashed line) to show its relation to water depth. Solid lines show the results of a piecewise regression with relevant change-points for PW salinity.....	50
4	Mean ($n=6$) $\pm$ 1 SE of monthly porewater sulfide at 15-cm depth at the freshwater (FW) and brackish water (BW) sites from the ambient-water	

	amended (+AMB) and saltwater amended (+SALT) plots.....	51
5	Change in <i>Cladium jamaicense</i> (sawgrass) culm density and aboveground live biomass over time at the freshwater (FW) and brackish water (BW) sites for the ambient amended (+AMB) and saltwater amended (+SALT) treatments. Points represent the monthly mean (n=6) $\pm$ 1 SE. Stars above the data point indicate that there was a significant (LSMEANS, $P < 0.10$) difference among treatments for that site.....	52
6	Annual mean (n=6) $\pm$ 1 SE of sawgrass aboveground net primary productivity (ANPP) separated by freshwater (FW) and brackish water (BW) site, ambient-water amended (+AMB) and saltwater-amended (+SALT) treatments, and year.....	53
7	Instantaneous rates (mean, n=4 $\pm$ 1 SE) of freshwater gross ecosystem productivity (a; GEP), ecosystem respiration of CO ₂ (b; ER), and net ecosystem productivity (c; NEP) and brackish water GEP (d), ER _{CO₂} (e), and NEP (f) over 2 years from both the freshwater and brackish sites. The bottom panel also plots water level (blue line) in relation to the soil surface over time. For figure clarity, the “no-chamber” control plots were not added, as they were not significantly different from the +AMB plots ($P > 0.10$). Stars represent months in which treatments were significantly different from each other (LSMEANS, $P < 0.10$).....	54
8	Estimated ecosystem C cycling over the two-year study period for net ecosystem productivity (NEP), gross ecosystem productivity (GEP), and ecosystem respiration of CO ₂ (ER _{CO₂}) from the freshwater (FW) and brackish water (BW) sites and how it changes ambient water (+AMB) or saltwater (+SALT) pulses. A negative NEP indicates that the marsh is a net C source to the atmosphere. Values represent mean (n=6) $\pm$ 1 SD flux over the experimental timeframe in g C m ⁻² y ⁻¹ . Annual flux was calculated using previously published GEP, PAR, ER, and temperature relationships for sawgrass (see Supplemental Methods) and previously derived light response curves for a sawgrass freshwater and brackish marsh (Neubauer 2013, Wilson et al. 2015).....	55
CHAPTER II		
1	Change in sawgrass aboveground live biomass over time for each treatment. Points represent the monthly mean (n=6 replicates per treatment) $\pm$ 1 SE.....	107
2	Measured aboveground net primary productivity (ANPP) separated by treatment and year. Letters represent the results of a Tukey’s post-hoc analysis performed separately for each year. Points represent the annual mean (n=6 replicates per treatment) $\pm$ 1 SE.....	108

3	Live aboveground (AG) and belowground (BG) biomass at the end of the experiment. Aboveground biomass was calculated allometrically, whereas belowground biomass was measured through soil coring down to 30-cm depth. Subscripted letters represent differences among treatments from a Tukey's HSD post-hoc test. Bars represent the mean ($n=6$ replicates per treatment) ± 1 SE in grams dry weight of material per meter squared. The number at the top of each treatment represents the ratio of aboveground to belowground biomass.....	109
4	Monthly soil CO ₂ efflux over time for each treatment. Points represent the monthly mean ($n=6$ replicates per treatment) ± 1 SE.....	110
5	Measured soil methane (CH ₄) efflux over the first year of the experiment. Points represent the monthly mean ($n=4$ replicates per treatment) ± 1 SE.....	111
6	Instantaneous flux of gross ecosystem productivity (a; GEP), ecosystem respiration of CO ₂ (b; ER), and net ecosystem productivity (c; NEP). Points represent the monthly mean ($n=4$ replicates per treatment) ± 1 SE...	112

CHAPTER III

1	Photographs taken in March 2015 in the brackish water portion of Everglades National Park showing (A) a group of sawgrass culms forming a pedestal and (B) a close up of the culms and exposed roots. The delineation between the bottom of the culms and the exposed roots indicates that the surface of the soil has collapsed about 30 cm (distance from bottom of the culm to current soil surface) over an unknown period of time.....	157
2	Daily soil CO ₂ efflux during the 8-day ramp-up period of the soil-only experiment in which salinity was raised by ~1 ppt every day in the elevated salinity monoliths from an ambient salinity of 10 ppt to an elevated salinity of 20 ppt. Salinity in the ambient salinity tanks remained relatively constant during this same period. Points represent the mean ($n = 6$ replicates) ± 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....	158
3	Soil CH ₄ ($n = 4$ replicates) and CO ₂ efflux ($n = 6$ replicates) over time for the soil-only experiment. Points represent means ± 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....	159
4	Soil CH ₄ ($n = 4$ replicates) and CO ₂ efflux ($n = 6$ replicates) over time for the plant-soil experiment. Points represent mean ± 1 SE. Amb =	

	Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....	160
5	Monthly instantaneous gross ecosystem productivity (GEP) (a), ecosystem respiration of CO ₂ (ER _{CO2}) (b), and net ecosystem productivity (NEP) (c) in micromoles of CO ₂ per meter squared per second over the experimental period for plant-soil experiment. A negative value indicates a flux of CO ₂ from the marsh to the atmosphere. Points represent means (n = 6 replicates) ± 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....	161
6	Mean (n = 6) ± 1 standard error of <i>Cladium jamaicense</i> (sawgrass) aboveground net primary productivity (ANPP) across the four treatments. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....	162
7	Schematic of estimated ecosystem C cycling for net ecosystem productivity (NEP), gross ecosystem productivity (GEP), ecosystem respiration of CO ₂ (ER _{CO2}), and soil CO ₂ efflux from the plant-soil experiment and how it changes with elevated salinity and/or water depth. Arrows pointing down indicate C entering the marsh, while upward pointing arrows indicate C leaving the marsh to the atmosphere. Values represent mean (n = 6) ± 1 SE flux over the experimental timeframe in g C m ⁻² y ⁻¹ , and the width of the arrows is scaled to the overall flux. Annual flux was calculated using established methods and previously derived light response curves for a <i>C. jamaicense</i> brackish water marsh (Neubauer, 2013; Wilson et al., 2015). Amb = Ambient salinity (10 ppt), Salt = Elevated salinity (20 ppt), Exp = Soil surface exposed 4-cm, Sub = Soil surface submerged.....	163
CHAPTER IV		
1	Photos showing peat collapse in the coastal Everglades 5 km inland. a, aerial photography showing open water ponds dotting the landscape. b, a group of sawgrass culms at ground level within this marsh. c, zoomed-in portion of photo b showing the delineation between the bottom of the culms and exposed roots. d, a recently collapsed sawgrass pedestal. Photo credits: a, S.E.D.; b-d, B.J.W.....	173
2	Soil elevation change relative to the elevation at the start of the experiment. Also plotted is water depth relative to the soil surface (blue line). Points represent mean (n=6) ± 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.....	179
3	Soil elevation change relative to the elevation at the start of two separate experiments. The data plotted come from this experiment (filled	

symbols) and from a similar mesocosm experiment on freshwater sawgrass peat monoliths (open symbols). All treatments were not subjected to drought and were completely inundated for the entire experimental period. Points represent mean ($n=6$) $\pm$ 1 SE. BW = brackish water, FW = freshwater, ppt = parts per thousand salinity.....179

- 4 Historical water level from a brackish water site in the Everglades. (a) Weekly mean ($n=7$) $\pm$ 1 SD water level at the brackish water site relative to the soil surface from 2001 to 2017. (b) Daily water level at the brackish water site from 2001 to 2017. The dashed line represents the soil surface, while the blue line represents either the water level during our one year mesocosm experiment (a) or the minimum water level in our drought experiment (-20 cm; b). Water level data comes from the USGS EDEN gauge NP6.....181
- 5 Ambient porewater and surface water salinity at the brackish water marsh. Mean ($n=6$) $\pm$ 1 SE of monthly porewater (PW) and surface water (SW) salinity (ppt) and daily water depth relative to the soil surface from the brackish water site within the +ambient-water plots (Wilson et al. in prep). Soil surface is plotted as the 0-cm water mark (dashed line) to show its relation to water depth. Solid black lines show the results of a piecewise regression with relevant change-points for PW salinity.....182

INTRODUCTION

Wetlands, although occupying only ~5-8% of the earth's surface, store 20-30% of soil carbon (C) because of their high productivity and low decomposition rate (Mitsch and Gosselink 2007, Nahlík and Fennessy 2016). Yet wetlands are highly susceptible to ecosystem fluctuations such as changes in hydrology, water chemistry, and vegetation regime (Deegan *et al.* 2012, Webster *et al.* 2013, Bernal *et al.* 2017). Coastal wetlands are particularly vulnerable to saltwater intrusion. Saltwater intrusion brings new ionic constituents (salts), an alternate source of nutrients, and altered hydrologic flow to coastal wetlands (Herbert *et al.* 2015). With average global sea level rising ~3 mm yr⁻¹ (Ryan and Law 2005), and recent increases up to 9 mm yr⁻¹ in some coastal areas (Wdowinski *et al.* 2016), saltwater intrusion in low-lying freshwater and brackish coastal wetlands will increase, potentially altering ecosystem C dynamics through effects on plants and soils (Valentine 2002, Whalen 2005).

Coastal peat marshes are susceptible to both saltwater intrusion and changes in water depth (Herbert *et al.* 2015, Whittle and Gallego-Sala 2016), but little is known about how exposure to saltwater affects organic matter accumulation and peat stability. In areas with low inorganic sediment input, peatland soils are highly organic (>85%) and vulnerable to external drivers such as freshwater diversion and effects of climate change (Nyman *et al.* 1990, Delaune *et al.* 1994, McVoy *et al.* 2011). The Everglades is the largest coastal peatland in the United States (>6000 km²; Richardson *et al.* 2008) and one of the most vulnerable to sea-level rise (SLR), as 60% of Everglades National Park is at or below 0.9 m in elevation (Pearlstine *et al.* 2010). Freshwater flow through the Everglades has been greatly reduced by compartmentalization through creation of water

storage areas and overall reduction in water delivery, resulting in less freshwater flow into the Everglades. SLR and reduced freshwater flow leaves the ecosystem highly vulnerable to saltwater intrusion (Light and Dineen 1994, Saha *et al.* 2011).

The term “peat collapse” has been used to describe a relatively rapid shift in soil C balance, leading to a net loss of organic C and loss of soil elevation, which culminates in a conversion of vegetated marsh to open water ponds (Delaune *et al.* 1994, Wanless and Vlaswinkel 2005). Peat collapse has been documented to varying degrees in different coastal wetlands and has been attributed to changes in microbial processes, increased sulfate reduction, sulfide accumulation, eutrophication from excess nitrogen (N) inputs, inadequate plant production, and vegetation damage from tropical storms. All of these factors could contribute to the instability of inland marshes (Delaune *et al.* 1994, Cahoon *et al.* 2003, Deegan *et al.* 2012, Voss *et al.* 2013). Areas of peat collapse have been observed in the brackish and saline marsh areas of the coastal Everglades, yet the mechanisms behind this collapse are not understood (Wanless and Vlaswinkel 2005, Chambers *et al.* 2015). *Therefore, understanding how factors associated with SLR that exacerbate saltwater intrusion in the coastal Everglades and potentially alter C storage and peat stability is critically important for the future of Everglades coastal wetlands.*

In the wetlands of the southern Everglades, the dynamic interplay between salinity, phosphorus (P) load, and inundation period controls ecosystem productivity (Childers *et al.* 2006, Troxler *et al.* 2014) and, thus, peat stability (Nyman *et al.* 2006, Baustian *et al.* 2012). Elevated salinity in coastal wetlands can produce plant morphological and physiological changes (Larcher 2003, Rejmankova and Macek 2008) that affect photosynthetic efficiencies, growth, maintenance, and nutrient uptake

(Pezeshki *et al.* 1987a, Pezeshki *et al.* 1987b, Neubauer 2013). The salinity stress on vegetation and decrease in productivity can decrease C inputs to the soil (Pezeshki *et al.* 1989, Neubauer 2013).

When saltwater intrudes into karstic systems such as the Everglades, P adsorbed to limestone bedrock can be replaced by cations within saltwater, increasing water soluble reactive phosphorus (SRP) concentrations. In oligotrophic wetlands, this newly available SRP can act as a subsidy to the wetland biota. Microbial community structure and processes respond rapidly to nutrient subsidies (Corstanje *et al.* 2007). In oligotrophic soils, P enrichment has been shown to stimulate microbial C processing and soil CO₂ production (Amador and Jones 1993, DeBusk and Reddy 1998, Wright and Reddy 2007, Medvedeff *et al.* 2015). Additionally, P enrichment can stimulate plant biomass growth and thus provide a C addition to the soil, though this response is usually much slower than the microbial decomposition response and can take years to produce visible change (Chiang *et al.* 2000, Noe *et al.* 2002). Nutrient additions can also change biomass allocation within wetland vegetation, generally causing more shoot over root production (Poorter and Nagel 2000). As peatlands rely on the input of root organic material for soil maintenance and stabilization, an influx of nutrients can actually destabilize and collapse the marsh (Deegan *et al.* 2012).

Finally, inundation period (water level relative to the soil surface) can have strong influence on the flow of C through the marsh. Under waterlogged conditions, production outpaces decomposition and C accumulates in soils over millennia. However, a shift in hydrology towards drier conditions, caused by either drought or drainage, can cause large amounts of stored C to be released to the atmosphere through enhanced aerobic

decomposition and can shift the ecosystem from a net C sink to a C source (Ise *et al.* 2008, Fenner and Freeman 2011, Wang *et al.* 2015). As stored C effluxes to the atmosphere, degradation of the soil structure can lead to a loss of soil elevation and a sudden (within a year) collapse of the peat (Cahoon *et al.* 2003). *Given accelerating SLR and greater saltwater intrusion into coastal wetlands, understanding how ecosystem productivity is affected by changes in the drivers associated with saltwater intrusion is crucial. Here, I test how elevated salinity, greater P loading, and changes in inundation regimes alter ecosystem productivity to influence peat collapse.*

In Chapter I, I conducted an *in situ* field experiment to investigate how soil biogeochemistry and ecosystem C cycling in a freshwater and brackish marsh are altered by monthly pulses of elevated salinity. Chapters II-IV expand on my field observations by investigating the effects of salinity, P, and inundation on freshwater and brackish marshes through controlled mesocosm experiments. I looked at how a “press” disturbance, in the form of elevated salinity, inundation, and nutrient loading, would impact ecosystem C and soil biogeochemical cycling. In chapter II, I conducted a mesocosm experiment to investigate how elevated salinity and increased P loading affects ecosystem function in a freshwater marsh. In chapter III, I conducted a mesocosm experiment to investigate how elevated salinity and increased inundation affect ecosystem function in a brackish water marsh. Finally, in chapter IV, I expanded on an observation made in chapter I, researching how drought combines with elevated salinity to influence ecosystem function. Chapter I is formatted to be submitted to *Ecological Applications*, Chapter II is formatted to be submitted to *Global Change Biology*, Chapter

III is formatted to be submitted to *Ecology*, and Chapter IV is formatted to be submitted to *Nature Climate Change*.

ABSTRACT

Coastal wetlands are globally important sinks of organic carbon (C). However, it is unknown to what extent wetland C cycling will be affected by accelerated sea-level rise (SLR) and saltwater intrusion, especially in coastal peat marshes where water flow is highly managed. Our objective was to determine how ecosystem C balance in coastal peat marshes changes with a doubling of salinity. For two years, we made monthly *in situ* manipulations of elevated salinity in freshwater (FW) and brackish water (BW) sites within Everglades National Park, FL, USA. Salinity pulses interacted with marsh-specific variability in seasonal hydroperiods whereby effects of elevated pulsed salinity on gross ecosystem productivity (GEP), ecosystem respiration (ER), and net ecosystem productivity (NEP) were dependent on marsh inundation level. We found little effect of elevated salinity on C cycling when both marsh sites were inundated, but, when water levels receded below the soil surface, the BW marsh shifted from a C sink to a C source. During these exposed periods, we observed an approximately 3-fold increase in CO₂ efflux from the marsh as a result of elevated salinity. Initially, elevated salinity pulses did not affect *Cladium jamaicense* biomass, but aboveground biomass began to be significantly lower in the saltwater amended plots after two years of exposure at the BW site. We found a 65% (FW) and 72% (BW) reduction in live root biomass in the soil after two years of exposure to elevated salinity pulses. Regardless of salinity treatment, the FW site was C neutral while the BW site was a strong C source (-334 to -454 g C m⁻² y⁻¹), particularly during dry-down events. A loss of live roots coupled with annual net CO₂ losses as marshes transition from FW to BW likely contribute to the collapse of peat soils observed in the coastal Everglades. As SLR increases the rate of saltwater intrusion

into coastal wetlands globally, understanding how water management influences C gains and losses from these systems is crucial. Under current Everglades' water management, drought lengthens marsh dry-down periods, which, coupled with saltwater intrusion, accelerates CO₂ loss from the marsh.

INTRODUCTION

Coastal wetlands are some of the most productive ecosystems in the world and are known for their capacity to store disproportionately large amounts of carbon (C) in their soils despite their relatively small global coverage (Chmura *et al.* 2003, Duarte *et al.* 2005, McLeod *et al.* 2011). Yet, storage of wetland C is highly vulnerable to changing environmental conditions, such as salinity and hydrology. With sea levels rising at ~3 mm y⁻¹ (Zhang *et al.* 2011), coastal freshwater and intertidal wetlands are being exposed to increased duration and spatial extent of inundation and potentially higher salinity water (Herbert *et al.* 2015).

The Florida Everglades, USA, is one of the largest wetland ecosystems in the world, an International Biosphere Reserve, a UNESCO World Heritage Site, and a Ramsar Wetland of International Importance. The Everglades contains vast amounts of C in its peat soils (Davis *et al.* 1994, Jerath *et al.* 2016); however, the Everglades contains only ~24% of its original peat volume because of anthropogenic modification (Hohner and Dreschel 2015), and climate change pressures keeps this wetland in a state of flux that may potentially alter its C storage capacity. In the early part of the 20th century, the construction of canals and levees diverted the flow of water away from the southern, coastal Everglades, reducing water tables by as much as 2.7 m and resulting in the loss of

half the ecosystem (McVoy *et al.* 2011; Sklar *et al. in press*). The reduction in freshwater flow into the southern Everglades has reduced the freshwater head, resulting in faster than expected saltwater intrusion into the Biscayne Aquifer which lies underneath the Everglades (Klein and Waller 1985, Saha *et al.* 2011). In addition to increased saltwater intrusion, less water flowing into the Everglades means more periods of “dry-down,” or when water recedes below the soil surface (Sklar *et al.* 2000). Extended dry-down periods can enhance C loss from the wetland through greater soil oxidation and microbial metabolism (Wright and Reddy 2001, Reddy and DeLaune 2008). As climate change is expected to change rainfall patterns in southern Florida (Allan and Soden 2008, Li *et al.* 2012), enhanced magnitude and increased dry-down events are possible (Obeysekera *et al.* 2015), which can further exacerbate saltwater intrusion and affect ecosystem C dynamics (see below). Steps have been taken to increase freshwater delivery to the coastal Everglades. Under the Comprehensive Everglades Restoration Plan (CERP) authorized in 2000, a series of 60+ projects were proposed to restore the flow of water back to the southern Everglades (Sklar *et al.* 2005). However, as of 2017, the most critical central decompartmentalization projects still await Federal funding and flows to the southern Everglades have not attained CERP target levels (National Academies of Sciences 2016). The continued intrusion of saltwater into the coastal Everglades has, in some areas, caused drastic changes to the landscape, such as “peat collapse” and the conversion of coastal marshes to open water ponds (Wanless and Vlaswinkel 2005).

In the low-lying and gently sloping coastal Everglades, the effects of saltwater intrusion may be amplified by a combination of a lower freshwater head, because of current water management strategies, and storm surges caused by tropical storms. Storm

surges bring pulses of saltwater into nearshore brackish-to-freshwater marshes that can impact ecosystem structure, function, and, ultimately, persistence (Herbert *et al.* 2015). Each pulse brings with it greater amounts of ionic constituents, such as Cl^- and SO_4^{2-} , normally not seen in high concentrations in these brackish to freshwater marshes. The initial conditions of the marsh likely determine how much these constituents will affect ecosystem functioning. For example, in historically freshwater marshes, pulses of elevated salinity water can cause ions, such as ammonium (NH_4^+), that are adsorbed onto cation exchange sites, to be displaced by ions found in seawater, such as Na^+ , Mg^{2+} , and Ca^{2+} (Seitzinger *et al.* 1991, Weston *et al.* 2010). The newly accessible NH_4^+ may be available for vascular plant uptake, especially in N-limited wetlands, but N uptake rates may slow as salt stress and sulfide (HS^-) toxicity suppress plant growth (Cormier *et al.* 2013). Increased SO_4^{2-} availability can increase microbial metabolism and the production of HS^- (Lamers *et al.* 1998, Weston *et al.* 2011), but also lead to a decrease in plant productivity as a consequence of sulfide toxicity (Spalding and Hester 2007, Lamers *et al.* 2013). While the effect on ecosystem C cycling of saltwater pulses into tidal marshes has been increasingly studied (e.g., Chambers *et al.* 2013, Neubauer 2013, Weston *et al.* 2014), the ecosystem C responses of non-tidal, nearshore freshwater and brackish marshes to saltwater pulses is still not well known.

Saltwater intrusion can lead to changes in soil biogeochemical cycling that affect ecosystem C dynamics (Weston *et al.* 2011, Herbert *et al.* 2015). Many studies have documented changes in C cycling along coastal marsh salinity gradients, often with contrasting results. Wilson *et al.* (2015) found that marshes along a salinity gradient in Mobile Bay, AL were losing CO_2 to the atmosphere, though it could not be determined if

this CO₂ loss resulted from seasonal saltwater intrusion or if this was an annual trend across sites. Weston *et al.* (2014) found that both tidal freshwater and mesohaline marshes in the Delaware River Estuary were relatively strong C sinks, while seasonal saltwater intrusion made the oligohaline marsh a net C source. Ardón *et al.* (2013) found that seasonal saltwater intrusion coupled with drought caused excess NH₄⁺ export from a North Carolina agricultural wetland. Most research to date on biogeochemical and ecosystem C cycling as a result of saltwater intrusion into coastal wetlands has focused on laboratory experiments (Weston *et al.* 2006, Chambers *et al.* 2011, Weston *et al.* 2011), mesocosm manipulations (Chambers *et al.* 2013, Wilson *et al. in review*), or natural salinity gradients (Craft *et al.* 2009, Giblin *et al.* 2010, Weston *et al.* 2014, Wilson *et al.* 2015, Whittle and Gallego-Sala 2016). Very few salinity manipulations have been conducted in the field (Neubauer 2013), but since scale often matters to results-interpretation, *in situ* manipulations are desirable for interpreting mechanisms of change inferred from smaller-scale/benchtop experiments or larger-scale descriptive studies.

Our objective was to test ecosystem responses to pulses of elevated salinity in both freshwater and brackish peat marshes in the coastal Everglades. We experimentally elevated *in situ* porewater salinity to twice-ambient levels using monthly pulsed deliveries to surface waters of brackish and freshwater marshes. We measured C fluxes (as CO₂ and CH₄), above- and below-ground *Cladium jamaicense* (sawgrass) biomass and production, and porewater biogeochemical constituents, to understand critical process changes in ecosystem function. We hypothesized that (1) prolonged exposure to pulsed salinity increases would alter belowground biogeochemical cycling and reduce

NEP in freshwater and brackish peat marshes; (2) the decline in NEP contributes to net soil C loss and less sawgrass fine root production; (3) C loss from the soil will be amplified during conditions of seasonal dry-down and/or drought; and (4) the FW marsh will be more sensitive to saltwater intrusion than the BW marsh and would therefore have higher magnitude responses to the elevated salt treatment.

MATERIALS AND METHODS

Study Sites and Experimental Design

This study was conducted in Everglades National Park, Florida, USA along the southeastern boundary of Shark River Slough, the largest drainage boundary in the southern Everglades. The coastal Everglades range along a gradient from freshwater sawgrass ridge and sloughs to coastal mangrove forests. We chose two sites for our study: a brackish marsh that was already experiencing saltwater intrusion, and a freshwater marsh that, to our knowledge, had not experienced elevated salinity. The brackish marsh (25°13'13.17" N, 80°50'36.96" W) was dominated by *Cladium jamaicense* (sawgrass) sparsely interspersed with *Conocarpus erectus* (buttonwood). The site was non-tidal and characterized by distinctive wet-dry hydrologic regimes in which the site was flooded for ~8 months of the year (mean since 2000, EDEN gauge NMP). The freshwater marsh (25°26'07.77" N, 80°46'51.50" W) was co-dominated by sawgrass and *Eleocharis cellulosa* (spikerush) but also contained other freshwater marsh plants such as *Crinum americanum* (swamp lily), *Bacopa monnieri* (waterhyssop), and *Panicum hemitomon* (maidencane). The hydrologic regime at the site was characterized as long-

hydroperiod, flooded nearly year-round (~11 months, mean since 2000, EDEN gauge NP62) during a typical year. The soil properties of each site can be found in Table 1.

In September 2014, 16 plots were established at each site along an 80-m long constructed boardwalk (Fig. 1). In twelve plots, we installed 1.4-m diameter, 0.4-m tall clear, cylindrical, polycarbonate chamber by inserting them 30-cm into the soil. We designated 4 additional plots as “no-chamber” controls and had no chamber installed around them. Each chamber had a movable collar with a series of 10-cm diameter holes that could be closed during application of dosing water and open to natural flow during all other times. Six ambient water addition (“+AMB”) plots were established upstream from natural water flow, while 6 treatment (+saltwater, “+SALT”) plots were established downstream of natural flow to avoid salt contamination into the +AMB and “no-chamber” control plots. The 4 “no-chamber” controls, which were interspersed within the +AMB plots (Fig. 1), did not receive water additions, and were only used for C flux measurements (*see below*). A 3-m “buffer zone” was established to avoid contamination between salt-dosing and control plots.

In Situ Saltwater Additions

Experimental water additions began in October 2014 and were conducted monthly for two years. The volume and salinity of brine solution mixed to deliver our dose varied for each dosing month to reach porewater concentration target. The volume and salinity of the brine solution was calculated on the basis of both water height from soil surface and surface water salinity so that we could reach an elevated salinity target in the porewater salinity, 2-5 ppt at the freshwater and 20 ppt at the brackish site. Our brine

solution during dosing ranged from 30.7-65.0 ppt at the FW site and 26.8-68.0 ppt at the BW site (Stachelek *et al. in review*). The dosing solution was prepared from a mixture of source water obtained either at or near each study site in combination with commercially available sea salt mix (Instant Ocean ®; Atkinson and Bingman 1997).

A movable collar on the chambers was used to close the chambers while dosing to ensure that the dosing water remained within the chamber. Doses were delivered from elevated boardwalks running alongside each chamber using a submersible bilge-style pump (Xylem Inc, USA). The outlet hose was fitted with a spreader device that split the large output stream into six smaller streams. The design was intended to maximize mixing with ambient site water while minimizing disturbance to sensitive benthic periphyton. Emergent plants were briefly sprayed with freshwater following dosing to avoid potential damage from direct salt application. Chambers remained closed for 24 hours to allow the elevated-salinity water to penetrate into the porewater, then chambers were opened to prevent closure artifacts.

Soil and Water Chemistry

Porewater salinity and nutrient measurements were made from three sampling wells (“sippers”) placed randomly inside each chamber to a depth of 15-cm. Porewater salinity was measured 24 and 120 hours after dosing. Two sippers were installed 0.5-m outside the edge of each chamber to monitor any potential leakage of saltwater outside of the treatment plots. Samples for nutrient and carbon analyses were collected 24 h after dosing. From each sipper, a ~25-mL sample was extracted after purging the length of tubing, and temperature, salinity, and pH were measured immediately in the field (YSI

Model 600 XL, Yellow Springs, OH). The porewater from each of the three wells was then combined into one sample per chamber, field filtered (0.7 μm GF/F), transferred to new, single use bottles, stored at 4°C, and analyzed within 21 d.

Surface water salinity was collected from each plot during wet periods by collecting 140-mL of sample water and processing it the same as we processed porewater. Surface water temperature, salinity, and pH were measured immediately in the field (YSI). Soluble reactive phosphorus (SRP) and total dissolved P (TDP) were analyzed at the South Florida Water Management District Analytical Research Laboratory on an Alpkem Flow Solution Analyzer (OI Analytical, College Station, TX, USA) following Standard Method 4500-P F (SRP) and Solorzano and Sharp (1980, TDP). Ammonium (NH_4^+), and dissolved inorganic N (DIN) were analyzed at the South Florida Water Management District Water Quality Laboratory on a Lachat Flow Injection Analyzer (Lachat Instruments, Loveland, CO, USA) following Standard Method 4500-NH₃ H (NH_4^+) or Standard Method 4500-N C (DIN). Dissolved organic C (DOC) was analyzed using a Shimadzu TOC-L analyzer (Shimadzu Scientific Instruments, Columbia, MD, USA) following Standard Method 5310 B. Alkalinity and pH were determined using an automated titrator (Metrohm 855 Titrator, Herisau, Switzerland) following Standard Method 2320 B (Alkalinity) and a modification to Standard Method 4500 H⁺ B (pH). Chloride (Cl^-) and sulfate (SO_4^{2-}) were measured using a Metrohm 881 Compact IC Pro System (Metrohm, Riverview, FL, USA) following Standard Method 4110 B. Sulfide (HS^-) was measured using standard methods (McKee *et al.* 1988). Soil redox potential was measured using standard techniques (Faulkner *et al.* 1989). Briefly, three platinum-tipped probes were inserted to 15-cm depth in each plot and allowed to

equilibrate for 30 minutes before measurement. Soil bulk density was determined by taking one 2.4-cm diameter core down to 30-cm. Samples were dried at 60°C and weighed to calculate dry bulk density (g cm^{-3}).

Species Richness, Culm Density, and Above- and Below-ground Biomass

Aboveground vegetation at each site was measured bimonthly using a non-destructive technique (Daoust and Childers 1998). Briefly, ten sawgrass plants per plot were tagged and turnover was determined from the change in the number of live and dead leaves. Within each plot during each sampling period, fifteen sawgrass plants were randomly chosen for number of leaves, height of the longest leaf, and culm diameter measurements. Average aboveground sawgrass biomass was then calculated using previously generated allometric equations (Childers *et al.* 2006). Sawgrass leaves were sampled yearly by collecting the youngest mature leaf from 3 randomly selected culms in each plot. They were then dried 60°C and ground before analysis for C, nitrogen (N; Zimmermann and Keefe 1997), and phosphorus (P; Solorzano and Sharp 1980) content. Macrophyte species richness was estimated by identifying and recording the genus and species of each plant type within each plot.

Live belowground root biomass was obtained by taking three 2.4-cm diameter soil cores from each plot at the end of year 2 (October 2016). Each core was taken to 30-cm depth, extruded, separated into 10-cm depths, and stored at 4°C until analysis (within 1 week). In the lab, the core segment was placed over a 1-mm sieve and washed with a constant stream of water. Live roots, those which floated when submerged in water, were separated from dead roots and peat, dried at 60°C, and weighed.

Ecosystem Carbon Flux

Within each plot, one 0.5 x 0.5 m polycarbonate collar was permanently installed 10-cm into the soil and extended 5-cm above the soil surface for ecosystem C flux measurements. Each collar had eight 2.5-cm diameter holes at soil surface level to allow for natural flow of water when measurements were not occurring. Plot-scale CO₂ exchange was measured monthly using a transparent static chamber (0.25 m² x 1.5 m; after Neubauer *et al.* 2000, Wilson *et al.* 2015). Prior to measurements being taken, each hole in the collar was plugged with a rubber stopper, the chamber was placed into a lip in the collar and sealed, and the system was allowed to equilibrate for 2 minutes. Measurements were then made for 3 minutes each in full light and in the dark, with the chamber lid removed in between each measurement to allow the chamber to return to atmospheric conditions (LI-COR 840, Lincoln, NE; Wilson *et al. in review*). All measurements made at each site were taken within ± 3 hours of solar noon and on the same day. Missing measurements occurred when there was either equipment failure (BW site, Jul – Aug 2016) or when water levels were higher than the boardwalk (FW site, Dec 2015 – Apr 2016), limiting access to the plots.

Methane (CH₄) exchange measurements were conducted monthly from October 2014 – February 2016. After the dark CO₂ exchange measurement was conducted, the chamber was kept in the dark and resealed for 20 minutes. Air from the chamber was continually pumped through a closed loop with a sampling port attached. Gas samples were taken 0, 10, and 20 minutes using a 60-mL syringe to withdraw 25-mL of air from the sampling port placed in line with the chamber. The sample was then injected into a 20-mL evacuated vial. Methane concentrations were determined using a gas

chromatograph (Hewlett-Packard 5890, Palo Alto, CA, USA), and the change in concentration over time was used to calculate the flux.

Soil respiration was measured using one 10-cm diameter collar installed 5-cm into the soil surface within each plot at each site to be taken during dry-down. Soil CO₂ efflux was measured over one 1-day period in February 2015 when water receded below the soil surface; it was measured for 120 seconds using a portable infrared gas analyzer (LI-COR 8100, Lincoln, NE, USA). Soil CO₂ efflux was not measured during other dry months because of equipment failure.

Statistical Analyses

The difference in biogeochemical variables (Cl⁻, SO₄²⁻, NH₄⁺, TDN, DOC, SRP, TDP, HS, alkalinity, and pH), gas flux (GEP, ER_{CO2}, ER_{CH4}, NEP, soil CO₂ efflux), culm density, and sawgrass biomass (above- and below-ground) among control, elevated salinity, ambient water dosing experimental plots were evaluated using linear mixed models (Package “nlme”, Pinheiro *et al.* 2017). Treatment and date were fixed factors, while plot was a random factor. Because hydrology highly influenced fluxes at the site, analyses for gas fluxes were performed separately when each site was wet (water covering soil surface) and dry (water below soil surface). A one-way ANOVA was used to compare differences in plant stoichiometry across treatments and sites. All linear mixed models were assessed for temporal differences using the least squared means (LSMEANS), with date as a model effect (R package *lsmeans*, Lenth 2017). All ANOVA analyses were sub-tested with Tukey’s post-hoc test to see differences among treatments. Differences in total belowground biomass, soil CO₂ efflux, and macrophyte species

richness were determined using an independent *t*-test. Normality and homoscedasticity were tested by visually inspecting plotted residuals, and data were log-transformed to increase heteroscedasticity when necessary. All of the above analyses were performed in R (R core team 2017). A piecewise regression with 200 iterations was used to determine change-points in ambient porewater salinity at the BW site using Sigmaplot 13.0 (Systat Software Inc., San Jose, CA). All analyses were tested with $\alpha=0.10$ because of the high within-site variability and because it was logistically unfeasible to increase replication power (Neubauer 2013). Therefore, type I errors (incorrectly rejecting the null hypothesis) are more likely than if a more conservative alpha value of 0.05 was used (Neubauer 2013).

RESULTS

Water Chemistry

Porewater salinity and chemistry at the FW and BW sites were measured 24-hours after dosing. Porewater salinity in the +SALT plots at the FW site ranged from 1.50 ± 0.29 to $4.56 \text{ ppt} \pm 0.30$ (mean $\pm$ SE; Fig. 2c) and was 2.39 ± 0.15 ppt higher compared to ambient fresh conditions (+AMB plots). Porewater salinity, pH, SO_4^{2-} , NH_4^+ , and TDN increased with added salinity, while porewater DOC decreased ($P<0.10$; Fig. 2). There was no change in temperature, alkalinity, SRP, and TDP with added salinity ($P>0.10$; Fig. 2). At the BW site, porewater salinity in the +SALT plots ranged from 11.24 ± 0.43 to $19.37 \text{ ppt} \pm 0.25$ (Fig. 2d). On average, porewater salinity was 4.71 ± 0.40 ppt higher in the +SALT plots compared to the +AMB plots. Porewater salinity and SO_4^{2-} increased with added salinity, while alkalinity, DOC, NH_4^+ , TDN, SRP, and TDP all decreased

with added salinity (Table 2; $P < 0.10$). Porewater SRP and TDP were 1-2 orders of magnitude higher at the BW site compared to the FW site.

Ambient porewater salinity at the BW site changed distinctly over the study period, elevating from 8.0 ± 0.3 ppt (Oct 2014) to 12.0 ± 0.4 ppt (Oct 2016; Fig. 3). Distinct change-points were detected using a 3-way piecewise regression ($r^2 = 0.943$, $F_{(7,24)} = 40.46$, $P < 0.001$) and corresponded with periods where water receded below or rose above the soil surface (Fig. 3). Mean salinity of each change-point can be found in Table S1.

Porewater HS^- was two orders of magnitude higher at the BW site compared to the FW site (Fig. 4). At the FW site, porewater HS^- was undetectable in the +AMB plots and elevated in the +SALT plots (0.08 ± 0.01 mM; $P < 0.001$). At the BW site, porewater HS^- was lower in the +SALT plots compared to the +AMB plots (1.20 ± 0.12 vs. 2.88 ± 0.12 mM; $P < 0.001$). There was no difference in redox potential between the +AMB and +SALT plots at the FW site (Fig. S2; $P = 0.252$). At the BW site, redox potential was significantly higher in the +SALT plots compared to the +AMB and “no-chamber” control plots (Fig. S2; $P < 0.001$).

Species Richness, Culm Density, and Above- and Below-ground Biomass

There was no difference in *E. cellulosa* stem density between the +AMB (185 ± 23 plants plot⁻¹) and +SALT (152 ± 21 plants plot⁻¹) plots at the FW site ($P > 0.10$). Macrophyte species richness at the FW site was not significantly different between the +AMB and +SALT treatments during the first year (4.1 ± 0.3 vs. 4.3 ± 0.2 species plot⁻¹, respectively); however, +SALT plots had fewer species per plot (2.9 ± 0.2) compared to

the +AMB treatment after the second year of dosing (3.8 ± 0.3 ; $t=3.77$, $P<0.001$).

Sawgrass leaf nutrient stoichiometry response to salt dosing varied by site (Table 3). At both sites, sawgrass C concentration did not change with saltwater addition (ANOVA, $P>0.10$). At the BW site, both sawgrass leaf N and P increased with added salinity after both 1 and 2 years (Table 3). Both sawgrass leaf N and P at the FW site were similar across treatments.

At the FW site, saltwater additions caused no change in sawgrass culm density or aboveground biomass after two years ($p>0.10$; Table 4, Fig. 5). At the BW site, there was a delayed response. Sawgrass culm density in the +SALT plots did not significantly differ from the +AMB plots until Oct 2016 (LSMEANS, $t=2.51$, $P=0.030$), two years after saltwater additions began. Similarly, we found no significant difference in aboveground biomass in +SALT plots until Dec 2016 (LSMEANS, $t=2.27$, $P=0.046$; Fig. 5a). ANPP was depressed in the second year at the BW site in the +SALT plots (307 ± 101 gdw m^{-2}) compared to the +AMB plots (504 ± 146 gdw m^{-2}), but this effect was not significant ($P>0.10$; Fig. 6). There was no change in ANPP with salt addition at the FW site ($P>0.10$). Sawgrass culm density, aboveground biomass, and ANPP were less at the FW site compared to the BW site; however, the effect was not significant with ANPP.

Two years after saltwater dosing was initiated, live belowground biomass at both sites decreased. At the BW site, live root biomass declined at all depths with added salinity ($F_{(1,30)}=6.69$, $P=0.014$), but this result was only significant in the top 10-cm and when all three depths were combined (Tukey HSD, $P<0.10$; Table 5). At the FW site, live root biomass declined at all depths with added salinity ($F_{(1,30)}=13.99$, $P<0.001$), but this result was only significant in the top 10-cm and when all three depths were combined

(Tukey HSD, $P < 0.10$; Table 5). There was no significant difference in live root biomass at 0-10 and 10-20 cm depths when comparing between the FW +AMB and the BW +AMB plots, yet the BW site had less live root biomass compared to the FW site at the 20-30 cm depth horizon ($t = 22.0$, $P = 0.004$) and with all combined depths ($t = 260.0$, $P = 0.022$; Table 5).

Ecosystem Carbon Flux

There was no difference between the “no-chamber” control and the +AMB plots for every flux measurement and on every date ($P > 0.10$; Table 6). Therefore, we only compare the results between the +SALT and +AMB plots. Rates of ER_{CO_2} and NEP had seasonal patterns at both sites (Fig. 7) directly related to inundation, with each site taking up CO_2 when inundated, but releasing CO_2 when water receded below the soil surface. ER_{CO_2} was directly correlated with water level, maxing out at $6.7 \mu mol CO_2 m^{-2} s^{-1}$ (BW, +SALT, Jul 2015) and $10.8 \mu mol CO_2 m^{-2} s^{-1}$ (FW, +AMB, Apr 2015) at each site when soil was exposed (Fig. 7). Overall, ER_{CO_2} was greater (ANOVA, $P < 0.10$) when soil was exposed at each site (Table 6).

At the FW site, added salt caused a reduction in NEP, GEP, and ER_{CO_2} ($P < 0.10$; Table 4) when the site was inundated, though this result was strongly time-dependent and occurred only for three months following dry-down (Fig. 7). There were no effects of elevated salinity on NEP, GEP, and ER_{CO_2} when the site FW was dry ($P > 0.10$; Table 6). When soil at the FW site was exposed, added salt caused greater ER_{CH_4} , however, because of high variability and lack of months in which the soil was exposed during drawdown, this result was not significant over the duration of the experiment ($P > 0.10$).

Soil CO₂ efflux during May 2015 was higher in the +AMB plots compared to the +SALT plots (1.27 ± 0.14 vs. 0.88 ± 0.05 $\mu\text{mol m}^{-2} \text{s}^{-1}$, respectively; $t=2.61$, $P=0.029$).

At the BW site, added salt had no effect on NEP, GEP, ER_{CO2}, ER_{CH4}, and soil CO₂ efflux ($P>0.10$; Table 4) when the site was wet (Table 6). When soil at the BW site was exposed, there was no difference between treatments ($P>0.10$) in GEP, ER_{CO2}, and ER_{CH4} flux, but added salt decreased NEP (more CO₂ released) compared to the “no-chamber” control and +AMB plots ($P=0.008$; Table 6). Soil CO₂ efflux during February 2015 was lower in the +AMB plots compared to the +SALT plots (0.60 ± 0.08 vs. 0.96 ± 0.10 $\mu\text{mol m}^{-2} \text{s}^{-1}$, respectively; $t=2.55$, $P=0.031$).

DISCUSSION

Salinity pulses significantly changed porewater biogeochemistry and the net soil C balance. Hydrology (i.e., seasonal dry-down) was an important factor that interacted with salinity pulses to influence NEP. Pulses of elevated salinity reduced NEP at the FW marsh following a dry-down event, while elevated salinity only changed ecosystem CO₂ flux from the BW marsh during dry-down conditions. The decline in live root biomass at both sites under conditions of elevated salinity reflected reduced organic matter inputs into the soil and/or increased turnover of live to dead roots. These results confirmed our hypotheses that pulses of elevated salinity water would change biogeochemical cycling and decrease plant root production and NEP, though the effect was site-dependent. We also confirmed that C loss was amplified during dry-down conditions at the BW site. We found that, even under ambient conditions, the BW marsh was a net CO₂ source to the atmosphere, a potential mechanism for the collapse of peat

observed at the site. Here we provide some of the first evidence of biogeochemical responses to simulated saltwater intrusion from non-tidal, coastal peat marshes.

Biogeochemical response to salinity pulses

Porewater chemistry varied dramatically by site in response to saltwater additions. Elevated salinity increased porewater SO_4^{2-} at both the FW and BW sites as the brine solution we applied to the marshes contained SO_4^{2-} concentrations mimicking those found in seawater. Elevated porewater SO_4^{2-} with saltwater intrusion has been shown to greatly influence marsh biogeochemical cycling. Under anaerobic conditions the addition of SO_4^{2-} encourage the sulfate-reducing bacteria to outcompete methanogens, given the higher energy yield that comes with using SO_4^{2-} as the terminal electron acceptor (DeLaune *et al.* 1983, Burdige 2006). Enhanced SO_4^{2-} reduction usually depresses CH_4 efflux and can initially stimulate soil CO_2 efflux (Chambers *et al.* 2011, Poffenbarger *et al.* 2011, Wilson *et al. in review*). We did not see a significant suppression in CH_4 efflux at either the FW or BW site, most likely because of the high variability among measurements and our inability to detect episodic ebullition flux at a monthly sampling frequency (Goodrich *et al.* 2011, Comas and Wright 2012, 2014). We expected CH_4 efflux to be much higher at the FW compared to the BW site based on higher salinity (Poffenbarger *et al.* 2011), but we saw little difference between the two sites (Table 6). High water levels during measured flux could have allowed CH_4 diffused from the soil into the overlying water column to be oxidized (Megonigal and Schlesinger 2002, Reddy and DeLaune 2008), and therefore, we may not have a true estimate of CH_4 production at our sites. Additionally, CH_4 efflux was likely not higher at the FW site because previous

work in the oligotrophic Everglades suggest that P limitation could be influencing CH₄ production (Amador and Jones 1993). Because of the long hydroperiods at our sites, they were covered with water at the outset of our study so we were not able to measure initial soil CO₂ efflux. Instead, soil CO₂ flux was measurable only when water receded below the soil surface (dry-down in Feb 2015; Fig. 7). During this time, with pulses of elevated salinity water, soil CO₂ efflux decreased at the FW site. This was most likely the result of microbial stress combined with more oxic conditions suppressing sulfate reduction and stimulating aerobic metabolism to the point where elevated SO₄²⁻ from saltwater addition would not stimulate sulfate reduction (Mitsch and Gosselink 2007, Weston *et al.* 2011). Conversely, elevated salinity stimulated soil CO₂ efflux at the BW site. The same result was seen briefly for a period of approximately one week in mesocosm experiments using soil harvested at the BW site when they were exposed to elevated salinity and dry-down conditions (Wilson *unpublished data*). Therefore, although pulses of elevated salinity coupled with dry-down may initially stimulate soil CO₂ efflux, this stimulatory effect may not persist.

Porewater NH₄⁺ and TDN increased with added salinity at the FW site, possibly as a result of cations from the saltwater mix replacing adsorbed cations in soils such as NH₄⁺ (Gardner *et al.* 1991, Ardon *et al.* 2013). Contrary to expectation, porewater alkalinity, DOC, NH₄⁺, TDN, SRP, TDP, and HS⁻ all decreased at the BW site with saltwater addition. Saltwater intrusion into coastal wetlands can happen from both aboveground pulses, such as tides or storm surges, or from belowground press factors, such as SLR and seasonal dry-down (Herbert *et al.* 2015). The biogeochemical response to each saltwater intrusion mechanism may also vary in a similar fashion. In our study,

there is evidence to suggest that lower porewater nutrient concentrations in the +SALT plots at the BW site may be caused by saltwater cation replacement. Our brine dosing solution mimicked the ionic composition of seawater, which is high in cations and is known to displace other cations adsorbed to soils, such as NH_4^+ and dissolved inorganic P (Gardner *et al.* 1991, Seitzinger *et al.* 1991, Fourqurean *et al.* 1992, Price *et al.* 2006). These minerals, now bioavailable, could have been taken up by macrophytes or microbes and incorporated into their biomass. Higher sawgrass leaf N and P content at our +SALT plots at the BW site compared to the +AMB plots corroborates this hypothesis. Higher leaf nutrient content within the +SALT plots could have also been caused by microbial cell death and lysis from excess salt, which would release nutrients and organic molecules into the surrounding porewater (Gobler *et al.* 1997) that can be taken up by the plants. This nutrient release could provide a temporary subsidy for brackish marsh plants to survive despite their relatively high-salinity and high-stress environments. More studies are needed to confirm this mechanism.

Ecosystem C cycling

Hydrology has been shown to strongly regulate exchange of CO_2 between the land and atmosphere in wetlands (Hao *et al.* 2011, Jimenez *et al.* 2012, Malone *et al.* 2013, Malone *et al.* 2014). The marshes we studied exhibited similar patterns of CO_2 flux in response to dry-down as other long-hydroperiod Everglades marshes by acting as a net CO_2 sink when water covered the soil surface and a net CO_2 source when water fell below the soil surface (Jimenez *et al.* 2012, Schedlbauer *et al.* 2012, Malone *et al.* 2014). During periods in which water was covering the soil surface, ER_{CO_2} was low and

maximum potential GEP was high at both sites, leading to net CO₂ uptake at solar noon (Fig. 7). However, during periods when water receded below the soil surface, ER_{CO2} spiked, as previous work illustrated higher aerobic respiration stimulation as a result of increased soil oxidation (Mitsch and Gosselink 2007, Webster *et al.* 2013), and these marshes switched from CO₂ sinks to net CO₂ sources to the atmosphere. GEP at our marsh sites was not affected during drought. Malone *et al.* (2013) saw a similar response in GEP and ER_{CO2} in a sawgrass marsh when exposed to dry-down conditions. To control for the addition of water in our +SALT plots, we added the same volume of ambient salinity water to our +AMB plots and took measurements on “no-chamber” control plots in which no water was added. We saw no difference in any flux measurements between the +AMB and no water-added control plots during either the wet or dry period (Table 6), meaning that the physical act of adding more water to the plot during dosing had no measureable effect. This was likely because the amount of ambient water we added to each plot (<200 L) was not enough to substantially raise water levels and affect GEP by decreasing exposed leaf area (Schedlbauer *et al.* 2010, Jimenez *et al.* 2012), and because water was already covering the surface, additional water dosing would not decrease ER_{CO2}, as seen in freshwater tidal marshes (Neubauer 2013).

Elevated salinity in coastal wetlands has been shown to alter ecosystem CO₂ cycling between the marsh and the atmosphere (Neubauer 2013, Weston *et al.* 2014). Our marsh sites responded differently to added salinity when water receded below the soil surface. When the marsh was wet, there was no effect on CO₂ flux with the addition of salinity, but when water receded below the soil surface, added salinity reduced NEP at the BW site (Table 6). Although mean GEP fell and mean ER_{CO2} rose during dry-down in

the added salinity plots at the BW site, these rates were not significantly different from the +AMB plots. NEP, however, was significantly greater in a negative direction, indicating that added salinity caused more CO₂ to be released to the atmosphere. The rise in ER_{CO2} with added salinity can be attributed to an increase in soil CO₂ efflux as oxidation of wetland soils generally enhances microbial respiration (Crow and Wieder 2005). Although we only have one month of soil CO₂ efflux measurements (Feb 2015), efflux increased by $0.35 \pm 0.09 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ with added salinity compared to the +AMB plots, while during the same month, ER_{CO2} increased by $0.51 \pm 0.31 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ with added salinity (Fig. 7e). Weston *et al.* (2011) measured a similar increase in soil CO₂ efflux with added salinity [0.60 (control) vs 0.71 (+salt) $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$] when tidal freshwater marsh soils were exposed.

Gross ecosystem productivity at the BW site also declined with added saltwater when no surface water was present (Fig. 7d). This response was a physiological effect because there was no significant decrease in biomass during this period (Fig. 5). Sulfide toxicity is a common stressor for wetland plants experiencing saltwater intrusion (Lamers *et al.* 1998). Lower sulfide and higher redox conditions in the +SALT plots at the BW site suggests that the plants were likely responding to osmotic stress of salt exposure rather than sulfide toxicity (Fig. 4, Fig. S2). During times of low water availability, salt can accumulate in soils because little water flushes through the marsh (Ardon *et al.* 2013, Weston *et al.* 2014). Saltwater addition raised porewater salinities to between 16 and 20 ppt during the period when water was continuously below the soil surface (~Feb to Aug 2015; Fig. 2). High salinity causes osmotic stress, which decreases stomatal conductance and inhibits photosynthesis on rapid timescales (Munns and Tester 2008). Sawgrass has

been shown to significantly decrease productivity with continuous exposure to 20 ppt salinity (Wilson *et al. in review*). Because of low water flushing, porewater salinity did not significantly decline between 1 and 5 days after saltwater addition during dry periods, meaning that salinity was maintained at or near levels known to lead to a reduction in NEP (Fig. S1; Wilson *et al. in review*).

At the FW site, saltwater addition significantly decreased both GEP and ER_{CO_2} , but only immediately following the dry-down event (Fig. 7a,b). This is a similar response to the decline in both GEP and ER that Neubauer (2013) found with saltwater additions to a tidal freshwater marsh and is expected given that GEP and ER are tightly linked (Cannell and Thornley 2000). Decreased GEP with saltwater after dry-down was likely triggered by dry-down and its legacy effects. Both GEP and ER were lower with added saltwater compared to the +AMB plots for 3 months post-dry-down, resulting in significantly less CO_2 uptake with added salt (Fig 7a-c). As little work has been done to study coupled saltwater intrusion and drought effects on coastal wetlands, it is hard to pinpoint the exact mechanisms behind this response. These months (Mar-Aug 2015) were the only time in which porewater salinity at the FW site rose above 4 ppt, potentially resulting in osmotic stress and inhibiting stomatal conductance (Fig. 2; Munns and Tester 2008). As water levels rose, the effectiveness of our saltwater dosing diminished and allowed the marsh to recover to pre-dry-down conditions.

Aboveground Biomass

The salinity tolerance of sawgrass-dominated marshes varies widely and is likely dependent on soil type, hydraulic conductivity, and cation exchange capacity. Sawgrass

has been shown to be tolerant of annual salinities up to 16.4 ppt, but require flushing with lower salinity water (<5 ppt) in order to maintain their productivity (Troxler *et al.* 2014). Some have shown that sawgrass productivity begins to decrease when exposed to salinities as low as 5 ppt (Macek and Rejmankova 2007), while others have shown that sawgrass does have some tolerance to salinity, and that aboveground biomass and productivity do not significantly decrease until continuous exposure of 20 ppt salinity (Wilson *et al. in review*). We expected to see a significant decline in sawgrass aboveground biomass with added salinity in the field. However, our results suggest that, aboveground, sawgrass is tolerant to frequent pulses of low-level salinity in freshwater marshes, as there was no decline in aboveground biomass and ANPP. Given that porewater salinity at the FW site never rose above 5 ppt, we would not expect to see much, if any, decline in aboveground biomass based on previous studies (Macek and Rejmankova 2007; Wilson *et al. in prep*). At brackish marshes, however, cumulative salt loading and hydrology appear to impact sawgrass aboveground biomass, GEP, and ANPP (Figs. 5, 7d). At our BW study site, porewater salinity in the +SALT treatment was much higher than the FW site and neared 20 ppt during some months. Because these were pulses of salinity applied monthly rather than continuously, porewater salinity trended downward towards ambient levels 5 days after saltwater was added (Fig. S1). We did observe lower culm density and aboveground biomass with added salinity compared to the +AMB plots toward the end of the 2-year sampling period at the BW site, and a non-significant decline in ANPP during the second year, indicating that increased exposure through continued pulses of elevated salinity appear to be having a negative effect on

sawgrass growth in these brackish conditions, though continued monitoring of increased salinity exposure is needed to confirm this.

Peat vulnerability to saltwater intrusion

In peat marshes that receive little to no sediment input, such as the coastal Everglades, root production and litter turnover is the primary driver of vertical peat accretion (Nyman *et al.* 2006, McKee 2011, Baustian *et al.* 2012). We measured a reduction in live root biomass with added salinity at both sites. Little is known about how salt stress reduces initiation of new seminal or lateral roots, although osmotic stress usually reduces cell expansion in root tips (Munns and Tester 2008). Macek and Rejmankova (2007) found that relatively low elevated salinity (4-5 ppt) also decreased sawgrass root biomass. Generally, our BW site had significantly less live root biomass compared to the FW site (Table 5). Given that ambient salinity at the BW site was ~8-12 ppt and that low levels of porewater salinity (<5 ppt) led to significantly less live root biomass at the FW site, this result was not surprising but has consequences for the future of peat stability. Peat is a matrix of mostly organic matter (typically >80%; Table 1) with high porosity (>85%; Nyman *et al.* 1990, Craft *et al.* 1993, Mitsch and Gosselink 2007). A loss of live roots, and thus the main input of organic matter, could lead to peat destabilization. Deegan *et al.* (2012) found that N-enrichment in New England salt marshes led to peat destabilization and creek bank erosion, as *Spartina alterniflora* root-to-shoot allocation declined. Saltwater intrusion as well has been directly related to increased peat decomposition and a decrease in C accumulation (Whittle and Gallego-Sala 2016). DeLaune *et al.* (1994) found that saltwater intrusion caused mass plant

mortality in a Gulf of Mexico brackish marsh, eventually resulting in peat collapse and conversion of the marsh to open water; the authors attributed this mainly to the loss of the living root network. The loss of the live root network in the peat soil matrix may be one mechanism leading to peat collapse at the BW site, evidenced by live standing sawgrass “pedestals” in which up to 30 cm of the root matrix is above the current soil surface (Wilson *et al. in review*).

Marshes should continue to accrete vertically if the amount of C entering the marsh is higher than amount of C leaving (Nyman *et al.* 2006, Weston *et al.* 2014). In non-tidal, non-riverine wetlands that receive little to no external organic matter inputs, such as sediments, estimating the soil C balance is a robust way to determine if a marsh is accumulating C. We took our instantaneous flux measurements, and, using previously established ecosystem productivity response curves and methods (*see Supplemental Methods*), we modeled GEP, ER_{CO_2} , and NEP to annual flux values (Neubauer 2013, Wilson *et al.* 2015). We found that NEP at the FW marsh was near C neutral (Fig. 8), which is what has been found at a nearby marsh using an eddy flux tower (Malone *et al.* 2014). Conversely, we found that the BW site was a large source of C to the atmosphere, even under ambient conditions (Fig. 8). Although not significant, pulses of elevated salinity led to a slight reduction in NEP at the FW site. A decline in live roots and organic matter input into the soil, coupled with a shift from the marsh to a net sink to a net source as it transitions from fresh to brackish, creates conditions that leaves coastal marshes vulnerable to collapse.

Water management effects on C flux

Water management decisions can play a critical role in determining how much water enters Everglades National Park (ENP; Light and Dineen 1994, Ross *et al.* 2003). Because continuous sheet flow through this system has been largely cutoff, periods of seasonal dry-down during low-rainfall years have a strong potential for altering freshwater marsh C cycling (Malone *et al.* 2014). We predicted that during one of these dry-down events, C loss from the soil would be amplified with pulses of elevated salinity water. However, our findings supported this hypothesis for the BW site only.

These results raise important questions regarding how seasonal dry-down influences salinity at brackish water marshes and how future saltwater intrusion could alter C cycling within these marshes. Extreme seasonal dry-down in coastal wetlands, most often a function of altered hydrology, water management, and drought, can (i) increase salinity by reducing flushing and causing salt ion accumulation, (ii) increase the upstream reach of brackish water, and (iii) increase the salinity of tidal water (Anderson and Lockaby 2012, Ardon *et al.* 2013). In most coastal wetlands, this high salinity pulse is seasonal and returns to ambient levels when flushed by upstream freshwater inputs (Ardon *et al.* 2013, Weston *et al.* 2014). However, in the Florida coastal Everglades, surface water flow has been highly modified and is much slower (mean $\sim 1 \text{ cm s}^{-1}$; Schaffranek 2004) than most surface flow-dominated wetlands (Light and Dineen 1994). This has reduced porewater flushing (Troxler *et al. in press*), allowed groundwater upwelling of high salinity water (Price *et al.* 2006), and contributed to a groundwater salt wedge that continues to move inland in ENP (Saha *et al.* 2011). Our results suggest that seasonal dry-downs, where the water table falls below the soil surface for an extended

period of time, may strongly control the ecological response of Everglades coastal wetlands to continued salinization.

Salt can accumulate in soils during seasonal dry-down and drought because little water flushes through the marsh (Ardon *et al.* 2013, Weston *et al.* 2014). During a period of low rainfall in early 2015, ambient porewater salinity at the BW site rose quickly in a 3-month period and maintained near constant higher salinity for the next year despite high rainfall that resulted in high water table levels and low surface water salinity (Fig. 3). This change-point directly coincided with when water dropped below the soil surface. Other change-points occurred every time water rose above or receded below the soil surface. Our results suggest that low rainfall exacerbates conditions of low freshwater delivery to produce extended dry-down and deeper drainage depth – a significant catalyst of change in this coastal Everglades peat marsh.

Coastal groundwater discharge (CGD), when seawater intrudes inland and forces brackish groundwater to discharge vertically into coastal wetlands, is a process that drives ecosystem dynamics in the coastal Everglades (Price *et al.* 2006, Harvey and McCormick 2009, Troxler *et al.* 2014). While CGD occurs year-round, seasonal hydrology drives its spatial extent (Dessu *et al.* 2018). During the wet season, the freshwater aquifer swells and creates a wedge, forcing the area of CGD further towards the coast, but during the dry season, the aquifer shrinks and allows the CGD zone to move more inland and further salinize brackish marshes (Troxler *et al. in press*). Within the Everglades, there is ample evidence in Taylor Slough of seasonal wetland salinization during the dry season (Troxler *et al. in press*) but less evidence from Shark River Slough (SRS), the location of our study. Price *et al.* (2006) showed no evidence of CGD within

SRS, but the wells sampled in this study were along a river and tidally influenced. However, CGD with salinities of ~25 ppt has been measured at West Lake, 1 km from our BW study site (Joshua Allen, Florida International University, unpublished data). Groundwater salinity of 5.5 ppt has also been measured at Nine Mile Pond, 5.9 km inland from our site (J. Allen, unpublished data). Therefore, it is likely that CGD strongly controls porewater salinity at these brackish marshes, especially during exceptionally dry periods, such as drought. While some predictions about how climate change will affect drought frequency are contradictory (Sheffield *et al.* 2012, Dai 2013), it is predicted that droughts will set in quicker and become more intense (Trenberth *et al.* 2014). Both CERP and the Central Everglades Planning Project aim to increase water flow to the coastal Everglades and could potentially mitigate the effects of drought by keeping coastal marshes inundated for longer periods. Without this restoration, periods of drought could further salinize these brackish marshes, cause more C to be released to the atmosphere (Fig. 8), and result in peat collapse and transformation of marsh into open water.

ACKNOWLEDGEMENTS

Funding for research was supported by Florida Sea Grant R/C-S-56, including cooperative agreements with the South Florida Water Management District, the Everglades Foundation, and Everglades National Park. Additional funding was provided through the National Science Foundation's Florida Coastal Everglades Long Term Ecological Research Program (DEB-1237517). We thank Shawn Abrahams, Michelle Blaha, Marbelys Garriga, Adam Hines, Rowan Johnson, Oliver Ljustina, Melinda Martinez, Fabiola Santamaria, Chris Sullivan, Frank Skiff, Emily Standen, Ryan Stolee,

and Mary Grace Thibault for help in the field. Len Scinto graciously provided lab resources for methane flux analysis. Joshua Allen provided descriptive details on coastal groundwater discharge in the coastal Everglades. Steve Oberbauer provided valuable feedback on early drafts of this manuscript. Benjamin Wilson was supported by a Florida International University Teaching Assistantship, Florida Sea Grant, FCE LTER and FIU Dissertation Year Fellowship. This is contribution xxxx of the Southeast Environmental Research Center.

FIGURES

Figure 1. Experimental setup at the FW site (not to scale). The setup was similar at the BW site. Sixteen plots were established along a boardwalk, with a 3-m buffer zone between the saltwater-amended plots and the ambient water-amended plots. “No-chamber” controls received no water additions. The +SALT plots were positioned downstream of flow to minimize contamination of the control plots.

Figure 2. Mean ($n=6$) $\pm$ 1 SE of monthly porewater temperature, salinity, pH, alkalinity, sulfate (SO_4^{2-}), dissolved organic carbon (DOC), ammonium (NH_4^+), total dissolved nitrogen (TDN), soluble reactive phosphorus (SRP), and total dissolved phosphorus (TDP) from the freshwater (FW) and brackish water (BW) sites over the two-year duration of the study taken at 15-cm depth from the ambient water (+AMB) and saltwater (+SALT) addition plots. Salinity is reported as parts per thousand, Alkalinity, SO_4^{2-} , DOC, NH_4^+ , and TDN are reported in mg L^{-1} , and SRP and TDP are reported in $\mu\text{g L}^{-1}$.

Figure 3. Mean ($n=6$) $\pm$ 1 SE of monthly porewater (PW) and surface water (SW) salinity and daily water depth from the brackish water site within the +ambient-water plots. Soil surface is plotted as the 0-cm water mark (dashed line) to show its relation to water depth. Solid lines show the results of a piecewise regression with relevant change-points for PW salinity

Figure 3. Mean ($n=6$) $\pm$ 1 SE of monthly porewater sulfide at 15-cm depth at the freshwater (FW) and brackish water (BW) sites from the ambient-water amended (+AMB) and saltwater amended (+SALT) plots.

Figure 4. Change in *Cladium jamaicense* (sawgrass) culm density and aboveground live biomass over time at the freshwater (FW) and brackish water (BW) sites for the ambient amended (+AMB) and saltwater amended (+SALT) treatments. Points represent the monthly mean ($n=6$) $\pm$ 1 SE. Stars above the data point indicate that there was a significant (LSMEANS, $P<0.10$) difference among treatments for that site.

Figure 5. Annual mean ($n=6$) $\pm$ 1 SE of sawgrass aboveground net primary productivity (ANPP) separated by freshwater (FW) and brackish water (BW) site, ambient-water amended (+AMB) and saltwater-amended (+SALT) treatments, and year.

Figure 6. Instantaneous rates (mean, $n=4 \pm 1$ SE) of freshwater gross ecosystem productivity (a; GEP), ecosystem respiration of CO₂ (b; ER), and net ecosystem productivity (c; NEP) and brackish water GEP (d), ER_{CO₂} (e), and NEP (f) over 2 years from both the freshwater and brackish sites. The bottom panel also plots water level (blue line) in relation to the soil surface over time. For figure clarity, the “no-chamber” control plots were not added, as they were not significantly different from the +AMB plots ($P>0.10$). Stars represent months in which treatments were significantly different from each other (LSMEANS, $P<0.10$).

Figure 7. Estimated ecosystem C cycling over the two-year study period for net ecosystem productivity (NEP), gross ecosystem productivity (GEP), and ecosystem respiration of CO₂ (ER_{CO2}) from the freshwater (FW) and brackish water (BW) sites and how it changes ambient water (+AMB) or saltwater (+SALT) pulses. A negative NEP indicates that the marsh is a net C source to the atmosphere. Values represent mean ($n=6$) $\pm$ 1 SD flux over the experimental timeframe in g C m⁻² y⁻¹. Annual flux was calculated using previously published GEP, PAR, ER, and temperature relationships for sawgrass (see Supplemental Methods) and previously derived light response curves for a sawgrass freshwater and brackish marsh (Neubauer 2013, Wilson *et al.* 2015).

TABLES

Table 1. Soil physicochemical properties (mean $\pm$ SE, $n = 6$) by site and by depth.

Site	Depth (cm)	Treatment	Bulk Density (g cm ⁻³)	Organic matter (%)	Total C (%)	Total N (%)	Total P (%)
Freshwater	0-10	+AMB	0.08 $\pm$ 0.03	83.2 $\pm$ 4.6	40.6 $\pm$ 2.7	3.29 $\pm$ 0.18	0.052 $\pm$ 0.007
		+SALT	0.11 $\pm$ 0.02	71.3 $\pm$ 4.4	35.2 $\pm$ 2.9	3.29 $\pm$ 0.18	0.057 $\pm$ 0.006
	10-20	+AMB	0.18 $\pm$ 0.06	70.2 $\pm$ 9.5	34.6 $\pm$ 5.5	2.80 $\pm$ 0.27	0.039 $\pm$ 0.008
		+SALT	0.18 $\pm$ 0.04	67.9 $\pm$ 7.9	31.0 $\pm$ 4.4	3.00 $\pm$ 0.23	0.052 $\pm$ 0.008
	20-30	+AMB	0.17 $\pm$ 0.03	63.2 $\pm$ 11.7	31.1 $\pm$ 5.5	2.51 $\pm$ 0.34	0.040 $\pm$ 0.010
		+SALT	0.22 $\pm$ 0.04	55.7 $\pm$ 9.4	25.9 $\pm$ 6.1	2.55 $\pm$ 0.50	0.042 $\pm$ 0.010

Table 5. Mean $\pm$ SE of net ecosystem productivity (NEP), gross ecosystem productivity (GEP), ecosystem respiration of CO₂ (ER_{CO2}), and ecosystem respiration of CH₄ (ER_{CH4}) from the brackish water (BW) and freshwater (FW) sites, separated by the “no-chamber” control, addition of ambient water (+AMB), and the addition of saltwater (+SALT) plots. Fluxes were separated into wet (water covering the soil surface) and dry (no surface water) periods. A negative NEP indicates a flux from the marsh to the atmosphere. Subscripts represent the results of a two-way repeated measures ANOVA. Values without superscripts indicates that there was no significant difference between treatments for that parameter.

CO ₂ and CH ₄ flux ($\mu\text{mol m}^{-2} \text{s}^{-1}$)

SUPPLEMENTAL INFORMATION

Fig S1. Porewater salinity 1 and 5 days post-dose for monthly doses over the 2-year dosing period.

Figure S2. Mean ($n=6$) $\pm$ 1 SE of monthly redox potential measured at 15-cm depth from the ambient-water amended (+AMB), saltwater amended (+SALT), and “no-chamber” control (no water added) plots at the freshwater (a) and brackish water (b) sites.

Table S1. Statistical table for the piecewise regression showing exact change-points and associated salinities in the +AMB plots at the brackish water site. Each y corresponds to mean $\pm$ 1 SE of measured porewater salinity measured at the beginning of the experiment (y1), each change-point (y2-4), and at the end of the experiment (y5). Each T corresponds to the mean $\pm$ SE of the day in which the salinity change-point occurred. The t and P values represent the results from the piecewise regression.

	Coefficient [salinity (ppt, y), Time (day, T)]	Std. Error (ppt, y, or days, T)	t	P
y1	8.0086	0.3621	22.1202	<0.0001

T3	Apr 20, 2016	62	9.1625	<0.0001

Supplemental Methods

Background

The ecosystem carbon (C) flux measurements for this experiment were only taken in full light and in the dark and only around solar noon. This measurement is the maximum potential gross ecosystem productivity (GEP) rate and does not account for changes in light level. Therefore, fluxes must be presented as either per second or per minute. In order to extrapolate out to a daily, monthly, and then annual rate, you must apply a modeling approach that revolves around empirical relationships between photosynthesis and light, and respiration and temperature (Neubauer 2013, Wilson *et al.* 2015). This was done separately for both the freshwater and brackish sites in our study.

Adaptation of light response curves

We chose to adapt light response curves from Wilson *et al.* (2015) because the curves produced in this study were also from Gulf of Mexico sawgrass-dominated marshes. We chose to use the curves from “Week’s Bay” for our freshwater site, and the curves from “Dog River” for our brackish water site. GEP measurements in the original study were taken at 4 or 5 different light levels from 3 plots each month for 1 year. For each month, we averaged the three PAR and flux measurements to create one relationship between the variables. We then calculated the percent change (PC) from the maximum for each light level and flux as:

$$PC = (P - P_o) / P_o \quad (1)$$

where P is the current parameter (PAR or GEP) and P_o is the maximum measured for that time period (Table 1).

PAR	GEP	PAR Percent Change	GEP Percent change
1414.67	2.98		
740.71	2.17	-0.48	-0.27
675.68	1.80	-0.52	-0.39
173.72	1.00	-0.88	-0.66
0.00	0.00	0.00	0.00

Table 1. Example of calculating percent change for February.

These PCs were then used to calculate the change in PAR and GEP based on measurements from that day that we measured flux. First, the maximum daily PAR value for each month from the current experiment was found from a nearby weather station (S331W, DBHydro, SFWMD). Then, the three middle light levels were assigned based on the PC from max calculated in eq. 1 (Table 2). Estimated GEP was calculated the same way using the measurement taken in full light (Table 2). This was repeated on all 12 plots ($n=6$) for each month.

Description	PAR	GEP	Description
Max PAR	1497	3.71	GEP measured in full light
Calculated PAR	783.8203582	2.697606332	Calculated GEP
Calculated PAR	715.0015092	2.247015708	Calculated GEP
Calculated PAR	183.8304713	1.249720552	Calculated GEP
	0	0	

Table 2. Estimated GEE for plot 5 in February 2015 based on PCs in PAR and GEP relative to the reference marsh. The calculated PAR and GEP are defined in Table 1.

After the relationships between PAR and GEP were calculated from each plot for each month, hyperbolic curves were fit to GEP vs. PAR for each according to:

$$GEP = [(a \times I)/(b + I)] \quad (2)$$

where I was incident irradiance ($\mu\text{mol m}^{-2} \text{s}^{-1}$), GEP was total photosynthetic uptake ($\mu\text{mol CO}_2 \text{m}^{-2} \text{s}^{-1}$), and a and b were empirically derived constants (Whiting *et al.* 1992). Best-fit regressions for the constants a and b were derived for each plot on a monthly basis using curve-fitting routine in Sigmaplot (v. 13.0, Systat Software Inc., San Jose, CA). Gross ecosystem productivity was calculated every 15 min by taking irradiance data averaged over 15 min time intervals (DBHydro, SFWMD) and integrating the results over a period in which PAR was above $10 \mu\text{mol m}^{-2} \text{s}^{-1}$ to obtain a daily gross photosynthetic uptake rate. This was modeled for every day of the year for two years, with each month using the derived a and b constants for that month, to get an annual rate.

Creation of respiration versus temperature curves

In order to model annual ecosystem respiration (ER), empirical relationships between ER and temperature were developed. Because seasonal hydrology greatly affects ER, ER vs. temperature relationships were developed separately for months when surface water was above the soil surface and months when surface water receded below the soil surface.

CO₂ fluxes taken in the dark from all sampling months with similar hydrology were regressed against air temperature (S331W, DBHydro, SFWMD) at the time of the measurement. Data were fitted to exponential curves using curve-fitting routine in SigmaPlot:

$$ER_{CO_2} = Ae^{B \times T} \quad (3)$$

where ER_{CO_2} was the ecosystem respiration of CO₂ rate ($\mu\text{mol C m}^{-2} \text{s}^{-1}$), T was air temperature ($^{\circ}\text{C}$), and A and B were empirically derived constants (Miller *et al.* 2001).

The curves allowed for the extrapolation of CO₂ respiration rates to all temperatures encountered during the sampling year. Two ER_{CO2} vs. T relationships was created for each site, one for months when the soil surface was inundated, and one for when water receded below the soil surface. These environmental relationships were then combined with air temperature data measured every 15 min (S331W, DBHydro, SFWMD) for 24 h to calculated daily ER_{CO2}. Similarly, daily-integrated NEE was calculated every 15 min from GEE and ER_{CO2} rates:

$$NEE = GEE + ER_{CO2} \quad (4)$$

where a positive NEE rate indicated net C assimilated through photosynthesis. The annual rate presented in this study is the average between the two years in which measurements were taken.

BALANCING NUTRIENT SUBSIDY AND SALINITY STRESS: SHORT- AND LONG-TERM EFFECTS OF SALTWATER INTRUSION ON FRESHWATER WETLAND ECOSYSTEM FUNCTIONS

Running Head: Saltwater intrusion in a freshwater wetland

Title: Balancing nutrient subsidy and salinity stress: short- and long-term effects of saltwater intrusion on freshwater wetland ecosystem functions

Key Words

sea-level rise, Florida Everglades, phosphorus, carbon cycling, coastal marsh

ABSTRACT

Environmental perturbations drive ecosystem functions through interacting subsidies and stressors. Effects of perturbations can switch from subsidy to stress, or vice versa, depending on the type and/or duration. Here, we assessed how coastal wetland ecosystem functioning responds to saltwater intrusion, a perturbation that is expected to greatly impact these ecosystems, given accelerating sea level rise. In wetland mesocosms, we continuously exposed macrophyte and peat soil monoliths from a freshwater *Cladium jamaicense* (sawgrass) marsh to two factors associated with saltwater intrusion in karstic ecosystems: elevated loading of salinity (a stress) and phosphorus (P) inputs (a subsidy). We took repeated measures using a 2 x 2 factorial experimental design ($n=6$) with treatments composed of elevated salinity (~ 9 ppt), P loading (0.45 mg P d^{-1}), or combination of both and looked at changes in water physicochemistry, ecosystem productivity, and plant biomass change over 2 years to assess short- and long-term subsidy-stress responses to saltwater intrusion. In the short-term, plants primarily exhibited subsidy effects with simulated saltwater intrusion (salinity +P), driven by increased P availability. Despite relatively high salinity levels (~ 9 ppt), gross ecosystem productivity (GEP), net ecosystem productivity (NEP), and aboveground biomass were significantly higher in the elevated salinity+P treated monoliths compared to the freshwater controls. Salinity stress effects became evident over time; although still higher than freshwater controls, GEP and NEP were significantly less in the elevated salinity+P treatment compared to the +P-only treatment. However, after 2 years of continuous exposure to elevated salinity, live root biomass was lower, regardless of whether P was added. Our results suggest that, although aboveground primary productivity may initially

be stimulated by saltwater intrusion, long-term exposure to elevated salinity will negatively impact belowground peat structure and stability. In addition, given that we found a strong negative response of root biomass but a strong positive response of aboveground biomass productivity to elevated salinity+P, the response variable measured is an important factor to consider when determining if ecosystem functioning is experiencing a subsidy or stress response to environmental perturbations.

INTRODUCTION

Environmental perturbations are common in coastal ecosystems and have the ability to strongly impact ecosystem functioning (Odum et al. 1995, Paerl 2006, Hanley et al. 2017). Although perturbations are typically viewed as a unimodal curve along a single axis (Odum et al. 1979), they can vary in frequency, magnitude, and direction of effect, which can strongly impact ecosystem processes, such as the flow of carbon (C) through the system (Shea et al. 2004, Hanley et al. 2017). For example, stochastic perturbations, such as hurricanes, can initially act as a stressor and negatively impact ecosystem functioning through defoliation and plant mortality (Cahoon et al. 2003, Zhang et al. 2008, Smith et al. 2009). However, over the long term, nutrient-rich sediments deposited by the same hurricane can act as a subsidy and positively impact ecosystem functioning (Castaneda-Moya et al. 2010, Barr et al. 2012, Danielson et al. 2017). Perturbations occurring as presses (i.e., continuous exposure) can have the opposite effect. For example, low to moderate press perturbations, such as flooding in riverine systems, can act as a subsidy, but high levels of flooding over a longer duration can act as a stress (Odum et al. 1979, Poff 2002, Wright et al. 2015). Understanding

functional responses and their direction to environmental perturbations is critical in ecosystems susceptible to rapid changes in climate.

Wetlands store 20-30% of global soil C, despite occupying only ~5-8% of the earth's surface, because of their high productivity and low decomposition rate (Mitsch and Gosselink 2007, Nahlik and Fennessy 2016). Wetland functions that determine C storage, however, are highly susceptible to perturbations, such as changes in hydrology, water chemistry, and vegetation regime (Deegan et al. 2012, Webster et al. 2013, Bernal et al. 2017). As sea level rise (SLR) accelerates, one perturbation likely to become more frequent is saltwater intrusion. Saltwater intrusion into historically freshwater coastal marshes will greatly affect wetland productivity and biogeochemical cycling. Saltwater can be a stressor for freshwater wetland vegetation and has been associated with decreased species richness (Sharpe and Baldwin 2012, Neubauer 2013), gross ecosystem productivity (Neubauer 2013, Wilson et al. *in review*), and primary production (Delaune et al. 1987, Spalding and Hester 2007, Herbert et al. 2015). In non-tidal, non-riverine, peat-dominated wetlands that do not receive an allochthonous sediment supply, a decline in productivity can be coupled with a decrease in soil organic matter inputs, which can negatively affect the stability of the marsh (Delaune et al. 1994, Baustian et al. 2012). Little work has been done to examine how ecosystem C processing in freshwater coastal peat marshes respond to saltwater intrusion, and whether elevated salinity makes these marshes more vulnerable to collapse (Wanless and Vlaswinkel 2005).

Saltwater intrusion into coastal wetlands occurs through two main pathways: overland incursion through tides or storm surge and groundwater upwelling (Herbert et al. 2015). In karstic systems, such as the Florida Everglades, porous limestone creates a

conduit for large-scale groundwater upwelling (Price et al. 2006). In freshwater marshes not adjacent to tidal creeks, groundwater upwelling of saline water is the most likely mechanism of saltwater intrusion into inland marshes (Price et al. 2006). This upwelling can have a large effect on the groundwater chemistry. Phosphorus commonly adsorbs to calcium carbonate bedrock, and an influx of saline groundwater can react with the limestone, causing P desorption and increasing water soluble reactive P (SRP) concentrations (Price et al. 2006, Flower et al. 2017). In oligotrophic wetlands, this newly available SRP can act as a subsidy in P-limited wetlands. Microbial community structure and processes can respond rapidly to nutrient subsidies (Corstanje et al. 2007). For example, in oligotrophic soils, P enrichment has been shown to stimulate microbial C processing and soil CO₂ production, which leads to a higher amount of C breakdown and faster turnover (Amador and Jones 1993, DeBusk and Reddy 1998, Wright and Reddy 2007, Medvedeff et al. 2015). Additionally, P enrichment can stimulate plant growth and biomass, thus providing organic inputs to the soil, although this response is usually much slower than the microbial response and can take years to manifest (Chiang et al. 2000, Noe et al. 2002). Nutrient additions can also change biomass allocation within wetland plants, generally causing more shoot relative to root production (Poorter and Nagel 2000). Given that peatlands rely on this input of autochthonous organic material for soil maintenance and stabilization, an influx of nutrients can potentially destabilize and collapse the marsh because of less root production (Deegan et al. 2012).

Saltwater intrusion into coastal, karstic wetlands provides an excellent case study to test perturbation theory given that exposure to saltwater is expected to act as both a subsidy (P) and a stress (elevated salinity) on the biological communities within these

ecosystems (Odum et al. 1979). Although there have been numerous studies on the effects of nutrient loading or elevated salinity alone on coastal wetlands, few very have looked at the interaction of subsidies and stressors that can occur with saltwater intrusion (Macek and Rejmankova 2007, Rejmankova and Macek 2008). The goal of this study was to determine how ecosystem productivity, biogeochemical cycling, and the greenhouse gas carbon balance respond to simulated saltwater intrusion into an oligotrophic freshwater karstic wetland. We chose the Florida Coastal Everglades as our study site because 60% of Everglades National Park (ENP) is at or below 0.9 m in elevation, a region highly susceptible to saltwater intrusion (Pearlstone et al. 2010). We hypothesized that increased salinity would initially stimulate soil CO₂ efflux, but that continuous exposure to elevated salinity would suppress soil CO₂ efflux over time. Conversely, we hypothesized that P addition would increase soil CO₂ efflux. We also hypothesized that increased salinity would reduce gross ecosystem productivity (GEP) and net ecosystem productivity (NEP), whereas P would increase GEP and NEP. We tested the subsidy-stress hypothesis that the interaction of salinity and P would offset lower GEP and NEP from increased salinity, resulting in no change in GEP and NEP compared to controls. Lastly, we hypothesized that the decrease in CH₄ efflux as a result of elevated salinity would be greater than the increase in CH₄ efflux with added P, shifting the greenhouse gas carbon balance.

MATERIALS AND METHODS

Study site and experimental facilities

In July 2014, twenty-four plant-peat soil monoliths (60 cm L x 40 cm W x 30 cm H) were collected from a freshwater marsh in the Everglades near Water Conservation Area 3B (25°46'07.4"N, 80°28'56.7"W) that was dominated by a dense stand of *Cladium jamaicense* (sawgrass). We extracted the peat monoliths using shovels to cut out a piece of marsh larger than a mesh-lined container (50 cm L × 40 cm W × 30 cm H). We then shaved the edges of the peat monoliths to the size of the container and placed each into mesh-lined containers filled with an array of 2.5 cm diameter holes to allow for water exchange but keeping soil structure intact. Monoliths were then transported to an outdoor mesocosm facility at the Florida Bay Interagency Science Center (FBISC) in Key Largo, FL.

Once on site, monoliths were placed into polycarbonate boxes (69 cm L x 51 cm W x 53 cm H) and randomly assigned to one of four treatments ($n=6$) interspersed among six large concrete tanks (2.2 m L x 0.8 m W x 0.7 m H; Fig. Sa). Each monolith was contained within its own water source and did not interact with any surrounding monoliths. The monoliths were allowed to acclimate for 7 months under inundated freshwater conditions before treatment manipulations and measurements began. The four treatments were Fresh (freshwater, no P), Fresh+P (freshwater with added P), Salt (elevated salinity, no P), and Salt+P (elevated salinity with added P). A partition was inserted between the no P and +P treatments to avoid possible contamination of water from one monolith splashing into another (Fig. S1).

In February 2015, water in the Salt treatments was added in gradually incrementing amounts of salinity over 2 months to hit our target salinity of 7 ppt, while P (2.25 mg L⁻¹ diluted phosphoric acid) was pumped to the appropriate treatments at a rate of 0.14 mL min⁻¹ (0.454 mg P day⁻¹, ~2x ambient load; (King and Richardson 2008). Dosing concentrations of salinity were adjusted monthly depending on porewater salinity in order to maintain a treatment level of ~7-10 ppt. Salinity was controlled by mixing water weekly to desired experimental salinity concentrations from four 2,000-gallon head tanks, two with freshwater and two with saltwater. Two liters of this water was manually added 2-3 times per week to each box in order to keep the monoliths completely inundated. Freshwater was collected from a nearby canal and had similar nutrient concentrations found in freshwater portions of the Everglades (C-111; 25°17'31.74" N, 80°27'21.59" W). Saltwater head tanks were equipped with a pump to draw water from adjacent Florida Bay. Nutrient concentrations of water added to the fresh and salt monoliths are reported in Table S1. Notably, the only significant difference between the two source waters was that bay water had higher salt concentrations, although NH₄⁺ was ~4x higher in the freshwater and SRP was ~3x higher in the bay water (Table S1).

Water physicochemistry and soil redox

Surface water in each monolith was collected monthly using a 60-mL syringe and placed into new, unused plastic bottles. Prior to the experiment, a porewater sipper with an air stone (4-cm long x 1-cm diameter) was inserted to 15-cm depth near the middle of each monolith. Porewater was collected weekly using a 60-mL syringe by placing suction on the sipper and evacuating at least 1 sipper volume before sampling. Filtered samples

were run through a 0.7- μm glass fiber filters (GFF) before being placed into a separate bottle. At the time of collection, temperature ($^{\circ}\text{C}$), salinity (ppt), and pH were measured on samples of freshwater source, saltwater source, and monolith surface water using a YSI Model 600 XL (Xylem, Inc., Yellow Springs, OH, USA). All water samples were stored at -20°C until analysis at the Southeast Environmental Research Center Nutrient Analysis Laboratory at Florida International University. Unfiltered surface water was analyzed for total N (TN), total P (TP), and total organic C (TOC). Filtered porewater and filtered surface water samples were analyzed for dissolved organic C (DOC), dissolved inorganic nitrogen (DIN; NO_3^- , NO_2^- , NH_4^+), and soluble reactive P (SRP). DIN, TN, TP, and SRP samples were analyzed on a Alpkem RFA 300 auto-analyzer (OI Analytical, College Station, TX, USA); TOC and DOC were analyzed with a Shimadzu 5000 TOC Analyzer (Shimadzu Scientific Instruments, Columbia, MD, USA). Sulfide (HS^-) was measured using standard methods (McKee et al. 1988).

Oxidation-reduction potential was measured using standard techniques (Faulkner et al. 1989). Briefly, three platinum-tipped probes were inserted to 5-cm depth in each monolith and allowed to equilibrate for 30 minutes until measurements were taken. Electrode potentials were corrected using a reference electrode and standard electrode potentials. Soil bulk density was calculated by taking one core ($2.4\text{ cm}^2 \times 30\text{ cm}$ depth) from each monolith. The core was separated into 10-cm sections, dried at 60°C , and weighed. The bulk density for each soil depth was calculated as the dry weight divided by the volume of the core segment.

Plant biomass and elemental stoichiometry

Sawgrass aboveground net primary productivity (ANPP) was measured every two months non-destructively following methods described in Daoust & Childers (1998). Briefly, sawgrass plants were tagged and measured bimonthly for the number of live and dead leaves, shoot height, and culm diameter. Change in sawgrass aboveground biomass and ANPP were calculated using previously derived allometric relationships between plant height, culm diameter, and biomass (Childers et al. 2006). Live belowground biomass was determined by taking one core ($2.4 \text{ cm}^2 \times 30 \text{ cm}$ depth) from each monolith at the end of the experiment, separating it into 10-cm sections, and storing it at 4°C until processing (within two weeks). The live roots, those which floated in water, were separated by washing through a 1-mm sieve, dried at 60°C , and weighed. Sawgrass leaf (year 1 & 2) and root (year 2) samples for each monolith were dried, ground, and subsampled for analysis of C, N (Zimmermann and Keefe 1997), and P (Solorzano and Sharp 1980) content.

Soil CO_2 and CH_4 fluxes

One 10-cm diameter PVC collar was installed 5-cm into the soil of each peat monolith for soil C efflux measurements. Soil CO_2 efflux ($n=6$ per treatment) was measured monthly near noon between Feb 2015 and Sep 2016 on all 24 monoliths using a portable infrared gas analyzer (LI-8100, LI-COR, Lincoln, NE, USA) equipped with a 10-cm diameter chamber. Each flux measurement was taken for 120s. The flux was calculated as the linear slope of CO_2 concentration over time. Soil CH_4 efflux was measured monthly between Feb and Nov 2015 from a subset ($n=4$ per treatment) of

monoliths using the LI-8100 modified to collect a subset of air for trace gas sampling. The chamber was sealed and, immediately following closure, 25-mL of gas was withdrawn using a 60-mL syringe from a port in-line with the instrument. After 15 min, another gas sample was collected. The gas was sealed in a 20-mL evacuated glass vial and transported back to the lab for analysis. Samples were run within 2 days of collection on a gas chromatograph (Shimadzu Scientific Instruments GC 8A, Columbia, MD, USA) fitted with a flame ionization detector (FID). Methane flux was calculated as the slope of CH₄ concentration over time. No soil gas flux measurements were taken in March, April, and December 2015, or January 2016 because of equipment failure.

Ecosystem CO₂ flux

Measurements of ecosystem CO₂ exchange were conducted bimonthly from Dec 2015 to Jan 2017 on a subset ($n=4$ per treatment) of monoliths. Prior to each measurement, a polycarbonate collar (67 L x 49 W x 58 H cm) was inserted between the container holding the monolith and the box containing the monolith and surrounding water. The collar was fitted with a foam platform on which the chamber could sit while enclosing both the plants and soil. The clear polycarbonate chamber (53 L x 38 W x 150 H cm) was placed onto the foam platform and sealed using bungee cords to ensure an airtight seal during measurements. A pump sent air from the chamber to an infrared gas analyzer (LI-840, LI-COR) and back to the chamber. The chamber was allowed to equilibrate for 2 mins, then CO₂ concentration was measured every second for 3 mins in both full light and in the dark (Wilson et al. in review). The flux was calculated as the linear slope of CO₂ concentration over time. Net ecosystem productivity (NEP) was

measured in full light, whereas ecosystem respiration of CO₂ (ER_{CO2}) was measured in the dark immediately after light measurements by covering the chamber with a dark cloth that blocked out all sunlight. Gross ecosystem productivity (GEP) was calculated from NEP and ER_{CO2} as:

$$-GEP = -NEP - ER_{CO2} \quad (1)$$

where NEP is instantaneous CO₂ flux (μmol m⁻² s⁻¹) in light and ER_{CO2} is the CO₂ flux in the dark. Ecosystem flux measurements were not taken from February to November 2015 because the experimental setup had not yet been equipped to handle these kinds of measurements.

Global greenhouse gas carbon balance contributions

The contribution of experimental peat-sawgrass monoliths to greenhouse gas C balance, and how it changes with added salinity and P, was estimated by comparing the overall mean NEP rates to overall mean soil CH₄ efflux (mol mol⁻¹) using the sustained-flux global warming potential (SGWP) of 45 for efflux and 203 for uptake for a 100 year time frame (Neubauer and Megonigal 2015). A new calculated NEP based on the SGWP was calculated as:

$$\text{Calculated NEP} = NEP - (CH_4 * SGWP) \quad (2)$$

Statistical Analyses

Statistical analyses were performed using R (R Core Team 2017). Differences in porewater physicochemistry, C flux, sawgrass biomass, and sawgrass ANPP among treatments were determined through linear mixed effects models (R package “nlme”,

Pinheiro *et al.* 2017). Treatment and date were set as fixed factors, and monolith number was set as a random factor. Following the mixed effects model, within-date differences in C flux, biomass, and ANPP were assessed with a standard least squares ANOVA, with date as a model effect (R package “lsmeans”, Lenth 2017). The effect of salinity and P on the overall mean C flux, biomass, ANPP, surface and source water physicochemistry, soil bulk density, and belowground biomass was determined using a two-way ANOVA, followed by a Tukey’s HSD post-hoc test to determine differences among treatments. Normality and homoscedasticity were tested by visually inspecting plotted residuals, and data were log-transformed to increase heteroscedasticity when necessary. All analyses used a significance factor of $\alpha = 0.05$.

RESULTS

Water physicochemistry and soil redox

Mean porewater salinity in the salinity treatments over the duration of the experiment was 8.83 ± 0.27 ppt (Table 1). In total, $84,933 \pm 1,717 \text{ g m}^{-3}$ of salt was added to each salinity treated sawgrass-peat monolith and $6.17 \pm 0.01 \text{ g m}^{-3}$ of P was added to each P treated sawgrass-peat monolith. Surface water DOC, TOC, NO_2^- , and TN were all higher in the saltwater amended monoliths (Table S2; $P < 0.05$). Surface water SRP and TP were higher with added P only in the saltwater monoliths. Porewater NO_2^- , NH_4^+ , DOC, SRP, and HS^- were all higher in the saltwater amended monoliths ($P < 0.05$) regardless of P addition ($P > 0.05$; Table 1, Table 2). Soil bulk density was lower in the Fresh+P and Salt+P monoliths (0.089 ± 0.012 and $0.079 \pm 0.011 \text{ g cm}^{-3}$, respectively) compared to the Fresh and Salt monoliths (0.102 ± 0.012 and $0.110 \pm 0.011 \text{ g cm}^{-3}$,

respectively) ($F_{(1,60)}=4.27$, $P=0.043$), whereas salinity had no effect ($F_{(1,60)}=0.01$, $P=0.907$). There was a significant effect of salinity, but not P, on soil redox potential (Table 2). Averaged over the duration of the experiment, soil redox potential at 15-cm depth was $+185.1 \pm 6.5$, $+180.4 \pm 6.5$, $+169.9 \pm 8.2$ mV, and $+147.5 \pm 8.1$ mV in the Fresh, Fresh+P, Salt, and Salt+P treatments, respectively.

Plant biomass and elemental stoichiometry

Sawgrass aboveground biomass remained relatively constant over the two-year study period in both the Fresh and Salt treatments, whereas aboveground biomass increased over time in the Fresh+P and Salt+P treatments (Fig. 1). On average, P had a significant effect on aboveground biomass and ANPP (Table 2). Beginning in June 2016, there was higher aboveground biomass in the Fresh+P treatment (LSMEANS, $P<0.05$). There was no difference among treatments in mean ANPP during the first year (Fig. 2, Tukey HSD, $P>0.05$). During the second year, ANPP was higher in both Fresh+P and Salt+P amended treatments, but this effect was only significant in the Fresh treatment (Tukey HSD, $P=0.007$). Sawgrass leaf stoichiometry was relatively consistent across treatments and years (Table S3). Leaf C and N content did not vary across treatments, and leaf P content was significantly higher in the Salt+P treatment compared to the Fresh treatment only during the first year (Tukey HSD, $P=0.002$). There was no interactive effect of salinity and P on either aboveground biomass or ANPP (Table 2).

Belowground biomass collected at the end of the study was significantly affected by elevated salinity ($F_{(1,67)}=8.50$, $P=0.004$) but not by added P ($F_{(1,67)}=2.58$, $P=0.112$). Elevated salinity decreased live root biomass by 32 and 53 % in the Salt and Salt+P

treatments, respectively (Fig. 3). The ratio of above- to below-ground biomass increased with both elevated salinity and added P (Fig. 3).

Soil CO₂ and CH₄ fluxes

Soil CO₂ efflux was dynamic across time but showed a strong trend of higher fluxes during warmer months (Fig. 4). There was no difference in CO₂ efflux among treatments during the first month, but within three months, elevated salinity began to depress CO₂ efflux (Fig. 4). On average, elevated salinity decreased soil CO₂ efflux by 41% and 61% within the Salt and Salt+P monoliths, respectively, whereas adding P had no effect (Table 2, Table 3). Soil CH₄ efflux showed a seasonal trend with higher efflux occurring during the warmer summer and fall months (Fig. 5). Elevated salinity decreased CH₄ efflux by 100% and 96% in the Salt and Salt+P monoliths, respectively, (Table 2, Table 3). Adding P increased soil CH₄ efflux by 403% in the Fresh+P monoliths, although this result was only marginally significant due to high variability ($P=0.057$, Table 2).

Ecosystem CO₂ flux

When ecosystem flux measurements began in December 2015, GEP and NEP were higher in the P amended treatments (LSMEANS, $P<0.001$) with no difference with added salinity (LSMEANS, $P=0.612$), whereas there was no effect of either salt or P on ER_{CO₂} (LSMEANS, $P>0.05$; Fig. 6). By the end of the two-year experiment, there was no difference in GEP, NEP, or ER_{CO₂} in the Salt treatment (LSMEANS, $P>0.05$), yet adding P caused GEP, NEP, and ER_{CO₂} to be higher in both the Fresh+P and Salt+P monoliths

(LSMEANS, $P < 0.05$). Over the course of the entire experiment, added P had a significant effect on NEP ($F_{(1,124)} = 56.47$, $P < 0.001$) whereas elevated salinity had no effect ($F_{(1,124)} = 2.40$, $P = 0.123$). Together, there was an interactive effect of salinity and P on NEP and GEP, but not ER_{CO_2} (Table 2). Mean NEP was significantly greater in the Fresh+P monoliths than the Salt+P monoliths (Tukey's HSD, $P = 0.027$). Cumulatively, added P increased GEP by 138% and 67%, ER_{CO_2} by 121% and 92%, and NEP by 136% and 62% in the Fresh+P and Salt+P monoliths, respectively (Table 3).

Contributions to global greenhouse carbon balance

Changes in contributions to the global greenhouse C balance occurred with the addition of both salinity and P. The $CH_4 : CO_2$ ratio was much smaller in the Salt and Salt+P monoliths compared to the Fresh and Fresh+P monoliths (Table 4). Elevated P greatly increased the $CH_4 : CO_2$ ratio in the freshwater monoliths, but had no effect in the elevated salinity monoliths. As a result, although the Fresh+P treatment had the highest measured NEP, increased CH_4 emissions associated with elevated P offset the increase in CO_2 uptake based on the SGWP (Table 4). Net ecosystem productivity, calculated incorporating the SGWP of CH_4 , showed that the Salt+P monoliths had the greatest NEP among all treatments.

DISCUSSION

Perturbation theory states that, although the input of some additional resource to an ecosystem may initially act as a subsidy, too much input over time may adversely affect ecosystem functioning (Odum et al. 1979). This theory is exemplified by saltwater

intrusion into karstic, freshwater wetlands which provides a supply of the limiting-nutrient, phosphorus (Price et al. 2006, Flower et al. 2017) while simultaneously introducing a physical stressor in the form of elevated salinity (Herbert et al. 2015). Effects of saltwater intrusion in karstic wetlands extends ideas of traditional perturbation theory in that the perturbation factor (saltwater) contains two sub-factors (i.e., salinity and P) that, in theory, should cause opposite responses in ecosystem function. In our study, the direction of saltwater perturbation depended on the variable measured. Aboveground, elevated salinity had no effect on plant biomass or ecosystem C exchange, but higher P availability increased both. However, belowground, elevated salinity reduced live root biomass whereas higher P availability had no effect. These results show that although saltwater intrusion into karstic, freshwater wetlands may initially stimulate ecosystem productivity, peat soil stability may become compromised. Below, we further examine the effects and implications of saltwater intrusion into freshwater wetlands.

Effects of salinity on plant biomass and C flux

The effects of elevated salinity on soil CO₂ and CH₄ efflux from freshwater marsh ecosystems vary in magnitude, duration, and direction (Setia et al. 2010, Chambers et al. 2011, Weston et al. 2011, Marton et al. 2012). We found that elevated salinity reduced soil CO₂ and soil CH₄ efflux an average of 52% and 98%, respectively (Table 3). Most saltwater manipulation studies on freshwater marsh soils to date have shown stimulatory effects of elevated salinity on soil CO₂ efflux (Weston et al. 2011, Marton et al. 2012). This response is usually attributed to an increase in SO₄²⁻ availability, which adds an electron acceptor for microbial metabolism and stimulates sulfate reduction (Capone and

Kiene 1988). However, we did not see this stimulatory effect. This could be because previous studies only examined low level salinity increases (~5 ppt; Weston et al. 2011, Marton et al. 2012), although salinity in our study was slightly higher (~9 ppt). Elevated salinity has been shown to cause osmotic stress for microbial communities and can even result in cell lysis (Wichern et al. 2006, Chambers et al. 2011). Given enough time, microbial communities adapted to higher salinities should replace those not adapted. In a similar mesocosm study, Wilson et al. (*in review*) found that raising salinity from 10 to 20 ppt had no effect on soil CO₂ efflux, but the mean overall flux was even lower (0.20-0.24 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) than fluxes measured at elevated salinity in the current study (0.48 – 0.55 $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$). It is possible that as freshwater marshes transition to brackish conditions, organic matter inputs to the soil decrease, resulting in less substrate for microbial communities to use for respiration. Then, as salt-tolerant vegetation becomes established, organic matter inputs increase and concurrently, so does microbial respiration. Another possible factor contributing to lower soil CO₂ efflux with elevated salinity is a reduction in root respiration, which can account for anywhere between 22 and 81% of overall soil respiration (Wang et al. 2006, Li et al. 2016). As freshwater vegetation becomes more stressed with elevated salinity, a reduction in root respiration is possible.

For many freshwater wetland plants, elevating salinity causes osmotic and ionic stress that can decrease aboveground biomass (Macek and Rejmankova 2007, Troxler et al. 2014), decrease root production (Charles et al. *in prep*), and shift the composition of species persistence in the marsh (Neubauer 2013). Although sawgrass is typically characterized as a freshwater wetland plant, it can persist under brackish water conditions

(Wilson et al. 2015), extending into areas of the coastal Everglades with mean annual salinities up to 16.4 ppt (Troxler et al. 2014). In our study, we found that elevated salinity ~9 ppt above ambient did not affect aboveground biomass after two years of continuous exposure (Fig. 3). However, Wilson et al. (*in review*) showed that elevating porewater salinity from 10 to 20 ppt in a similar mesocosm experiment significantly decreased sawgrass GEP and ANPP. Therefore, there appears to be a salinity “tipping point” between 10 to 20 ppt in which sawgrass productivity is significantly affected. In a field survey within the estuarine ecotone of the Everglades, Troxler *et al.* (2014) found that the number of days in which surface water salinity exceeded 30 ppt was significantly correlated with decreased sawgrass ANPP, but when the marsh was flushed with low salinity water (< 5 ppt), ANPP was unaffected by previous exposure to high salinity. The results of our study and others (Troxler et al. 2014) suggest that flushing by low salinity water is crucial for maintaining high productivity in sawgrass within the estuarine ecotone of the Everglades.

Although we found no decrease in GEP or ANPP with salinity elevated to ~9 ppt, there was a significant decrease in live root biomass after two years of elevated salinity exposure, suggesting that elevated salinity is affecting belowground plant production. Elevated salinity in coastal wetlands has been shown to have a disproportionately larger effect on root rather than shoot growth (Rozema and Blom 1977, Janousek and Mayo 2013). Faster live-to-dead turnover of roots with added salinity likely created a new source of DOC (Hansson et al. 2010) and may explain why porewater DOC was much higher in the saltwater-amended monoliths than the freshwater monoliths. As roots die, DOC can be leached abiotically out of the soil and usually provides an additional energy

source for bacteria (Pinney et al. 2000). However, we saw a decrease in soil CO₂ efflux with increased salinity, which means that the microbial community was likely too stressed to use this newly available energy source (Schimel et al. 2007). In addition, we saw higher DOC content in the surface water, indicating that this newly produced DOC was interacting with the water column (Table S2). Therefore, saltwater intrusion has the potential to increase DOC export to downstream estuaries. This finding runs counter to other studies that show either no change or a decrease in porewater DOC and export with saltwater intrusion into freshwater wetlands (Weston et al. 2011, Ardon et al. 2016). Soil core experiments, like those performed in Weston et al. (2011) and Ardon et al. (2016), likely contain little to no live roots, and therefore an increase in DOC leaching from dying plant roots would not have been seen.

Effects of P on plant biomass and C flux

In coastal wetlands, additional nutrient loading usually leads to an increase in soil respiration (Morris and Bradley 1999, Wigand et al. 2009). In the Everglades, P is the main limiting nutrient (Noe et al. 2001). In the northern Everglades, P from fertilizer runoff has been shown to stimulate soil CO₂ efflux by 36% (Wright and Reddy 2007) and accelerate peat decomposition (Amador and Jones 1993, Qualls and Richardson 2008). We expected that an increase in P load would stimulate soil CO₂ efflux; however, we found that adding P had no effect. The P loading rate in our experiment was low and only twice the ambient rate (King and Richardson 2008), potentially too low a dose to have a stimulatory effect on soil respiration. In nutrient-poor freshwater wetlands, such as the Everglades, high nutrient levels have also typically been correlated with higher CH₄

production (Drake et al. 1996, Wright and Reddy 2001). We found that increased P loading stimulated soil CH₄ by 96% in the freshwater monoliths, although because of high monthly variability, this effect was only marginally significant ($P = 0.057$). These results are similar to those by Holmes et al. (2014) who found a fourfold increase in soil CH₄ efflux in a P enriched site compared to a nearby unenriched site. We may be underestimating the total CH₄ flux from the marsh because we did not measure CH₄ loss from the vegetation. Despite previous work suggesting that sawgrass does not have active gas transport through its aerenchyma (Chabbi et al. 2000), loss of CH₄ through sawgrass stems has been measured in the Everglades and could account for a substantial portion of total CH₄ efflux from the marsh (Steven Oberbauer, Florida International University, pers. comm.)

Inputs of limiting nutrient in oligotrophic wetlands can have both positive and negative effects in regard to marsh stability. Additions of limiting nutrients can stimulate both shoot and root production, increasing organic matter inputs into the soil (Macek and Rejmankova 2007). However, addition of nutrients may shift resource ratios and alter biomass allocation towards less root production, which in turn decreases organic input into the soil and could potentially leave it vulnerable to collapse (Tilman 1985, Castaneda-Moya et al. 2011, Deegan et al. 2012). We found that an increase in P loading significantly increased aboveground biomass, GEP, ER, and NEP (Table 3), but these results were not seen until the second year of P addition (Fig. 1, Fig. 2). In a similar study, Macek and Rejmankova (2007) found that P addition had no effect on sawgrass growth; however, their study lasted only 2 months. Sawgrass response to P enrichment is often slow, which is what typically allows cattails to outcompete sawgrass in the P-

enriched northern Everglades (Lorenzen et al. 2001, Webb and Zhang 2013). We did not see an increase in macrophyte total P (TP) content after two years, which is consistent with results from a long-term P addition study in the Everglades that found that it took 3-4 years of continuous low-level P addition to see a change in macrophyte TP, although the dominant species in that study was *Eleocharis cellulosa* (Gaiser et al. 2005). Although not significant, live belowground root biomass after two years was higher in the P amended freshwater monoliths (Fig. 3), and root ingrowth doubled with P addition, regardless of the presence of salinity (Charles et al. *in prep*). However, added P shifted the shoot to root ratio towards more shoots and less roots in both the freshwater and saltwater monoliths, indicating a change in biomass allocation with the addition of P. Deegan et al. (2012) saw a similar shift in biomass allocation in a New England salt marsh with nutrient additions, a result they suggested caused increased erosion and collapse of the marsh. In addition to a shift in biomass allocation, we saw a reduction in soil bulk density with added P, indicating that P additions alone could begin to destabilize the marsh.

Saltwater intrusion: a subsidy or a stress?

The exposure and duration of perturbations in coastal ecosystems can strongly influence the magnitude and direction of ecosystem functioning to a disturbance event and influence if the perturbation factor is a stress or a subsidy (Odum et al. 1979, Wright et al. 2015, Hanley et al. 2017). For example, wrack deposition in coastal marshes can be a strong stress to many ecosystem functions over the short term, but when viewed over a longer period, that stress affect can be alleviated by the additional delivery of nutrients

that comes with deposition (Hanley et al. 2017). Here, we were able to determine the responses of some ecosystem functions to saltwater intrusion over both the short-term (monthly repeated measures) and long-term (2-year manipulation).

In our study, we found that the main forcing factor with saltwater intrusion (elevated salinity or increased P) was dependent on the variable measured. Net ecosystem productivity was greatly enhanced with added P, mainly because of increased plant productivity, whereas elevated salinity had no effect on both NEP and ANPP. However, two years may not have been long enough to see the full effect of salinity on primary productivity. During the final months of measurements, NEP in the Salt+P treatment was significantly less than the Fresh+P treatment (Fig. 6c), potentially indicating that NEP had already plateaued and was trending downward because of continued salt stress as perturbation duration increased (Odum et al. 1979). Salt had a much stronger influence than P on both soil CO₂ and CH₄ efflux, which both decreased with elevated salinity (Table 3).

Although the response of NEP to P in the Salt+P treatment was greater than the response to salinity, it is important to examine how all responses to saltwater intrusion altered the greenhouse gas C balance. The contribution to greenhouse gas C balance accounts for not only the instantaneous uptake of CO₂, but also the long-term radiative forcing of CH₄ emitted to the atmosphere (Neubauer and Megonigal 2015). In our study, salinity strongly suppressed CH₄ efflux, whereas increased P loading stimulated CH₄ efflux, but only from the freshwater monoliths. Thus, saltwater intrusion, when coupled with increased P loading, had higher calculated NEP, and therefore a larger sink of CO₂-eq C, than the freshwater control when accounting for the SGWP (Table 4). Although

saltwater intrusion may initially increase the greenhouse gas C balance in a positive way, the overall health and survival of the marsh does not only depend on aboveground productivity (see below).

Saltwater intrusion into coastal wetlands is a current pressing issue because of the potential for elevated salinity to suppress ecosystem productivity in the short term. In non-tidal marshes without allochthonous sediment inputs, such as the Everglades, peat soils are formed primarily through organic matter inputs (Baustian et al. 2012). If saltwater disrupts the processes that form peat, peat may collapse. Although we found no decrease in GEP or ANPP with elevated salinity, there was a significant decrease in live root biomass. A decrease in live roots could result in less root binding of soil, causing the soils to begin to slump and collapse (Delaune et al. 1994). Another study conducted on the same mesocosm monoliths used in this study found that elevated salinity caused ~2-cm in elevation loss after only one year, whereas adding P had no effect (Charles et al. *in prep*). Therefore, even though aboveground productivity and NEP were unaffected by elevated salinity, soil structure and integrity appear to be negatively affected by salt and thus vulnerable to collapse. This finding would explain the presence of live sawgrass “pedestals” in the brackish portions of the Everglades (ambient salinity ~10 ppt), where it appears that the surrounding soil has collapsed (Wilson et al. *in review*). Although saltwater intrusion into freshwater wetlands may initially stimulate primary productivity through a P subsidy, the impact of elevated salinity on root and soil structure may ultimately be what matters to the survival or collapse of these marshes.

ACKNOWLEDGEMENTS

Funding for research was supported by National Science Foundation's Florida Coastal Everglades Long Term Ecological Research Program (DEB-1237517). Additional funding was provided through Florida Sea Grant R/C-S-56, including cooperative agreements with the Everglades Section of the South Florida Water Management District, the Everglades Foundation, and Everglades National Park. We are grateful to the State of Florida Department of Transportation Region 6 Office for working with us to gain permission to access and harvest peat for this experiment. We thank Laura Bauman, Rowan Johnson, Michael Kline, Michelle Robinson, and Ryan Stolee for help in the field. Thank you to Len Scinto for use of his GC for methane measurements. Steve Oberbauer provided valuable feedback on early drafts of this manuscript. Benjamin Wilson was supported by a Florida International University (FIU) Teaching Assistantship and FIU Dissertation Year Fellowship. This is contribution xxxx of the Southeast Environmental Research Center.

Salt+P	27.1 ± 0.4	8.63 ± 0.26 ^b	6.70 ± 0.02 ^b	3268 ± 106 ^b	0.25 ± 0.013 ^b	0.27 ± 0.03	28.60 ± 3.45 ^b	0.39 ± 0.02 ^b	0.209 ± 0.019 ^b

Data represent mean ($n=6$ replicates) $\pm$ 1 standard error of temperature, salinity, pH, and dissolved porewater constituents averaged across treatments. DOC, NO₂⁻, NO₃⁻, NH₄⁺, and SRP are in $\mu\text{mol L}^{-1}$, HS⁻ is in mM. Letters represent significant differences among treatments from a multiple comparison test (LSMEANS, Tukey adjusted).

DOC dissolved organic carbon, NO₂⁻ nitrate, NO₃⁻ nitrite, NH₄⁺ ammonium, SRP soluble reactive phosphorus, HS⁻ sulfide.

Table 2. Full statistical results for the linear mixed model.

Model run with time as an independent variable for temperature, salinity, pH, dissolved porewater constituents, ecosystem C flux, biomass, and redox. Interpreted results are in bold. Data presented as $F(\text{numerator degrees of freedom, denominator degrees of freedom}) = F \text{ value}, P = P \text{ value}$. DOC, TOC, NO_2^- , NO_3^- , NH_4^+ , and SRP are in $\mu\text{mol L}^{-1}$. Interpreted results are in bold. *DOC* dissolved organic carbon, *NH₄⁺* ammonium, *TDN* total dissolved nitrogen, *SO₄²⁻* sulfate, *TDP* total dissolved phosphorus, *SRP* soluble reactive phosphorus, *GEP* gross ecosystem productivity, *ER_{CO2}* ecosystem respiration of CO₂, *NEP* net ecosystem productivity, *ANPP* aboveground net primary productivity.

Table 3. Averaged carbon flux measured over the experimental period.

Treatment	NEP	GEP	ER_{CO2}	Soil CO₂	Soil CH₄
Fresh	5.3 ± 0.5 ^a	6.6 ± 0.5 ^a	1.4 ± 0.2 ^a	0.93 ± 0.08 ^a	9.3 ± 5.0 ^{ab}
Fresh+P	12.5 ± 2.1 ^b	15.8 ± 2.9 ^b	3.2 ± 0.7 ^b	1.23 ± 0.12 ^a	35.2 ± 12.9 ^a
Salt	6.0 ± 0.8 ^a	7.4 ± 1.1 ^a	1.4 ± 0.3 ^a	0.55 ± 0.07 ^b	-0.01 ± 0.77 ^b
Salt+P	9.6 ± 1.3 ^b	12.3 ± 1.7 ^b	2.7 ± 0.5 ^{ab}	0.48 ± 0.07 ^b	1.4 ± 0.6 ^{ab}

Data represent the mean ($n= 4$ or 6) $\pm$ 1 SE of net ecosystem productivity (NEP), gross ecosystem productivity (GEP), ecosystem respiration of CO₂ (ER_{CO2}), soil CO₂ (all in $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$), and soil CH₄ flux ($\text{nmol CH}_4 \text{ m}^{-2} \text{ s}^{-1}$) from each treatment over the duration of the experiment. Letters represent significant differences among treatments from a multiple comparison test (LSMEANS, Tukey adjusted).

Table 4. Calculated sustained-flux global warming potential (SGWP) over a 100-year period and corrected net ecosystem productivity (NEP) accounting for the contribution of methane (CH₄) to the global greenhouse carbon balance.

	CH₄	SGWP	NEP	Corrected NEP	CH₄ : CO₂
Fresh	0.024 ± 0.013	1.11 ± 0.59	3.81 ± 0.39	2.70 ± 0.49	0.291
Fresh+P	0.092 ± 0.034	4.18 ± 1.53	8.99 ± 1.53	4.80 ± 1.53	0.466
Salt	0.000 ± 0.000	-0.00 ± 0.10	4.28 ± 0.54	4.28 ± 0.32	-0.001
Salt+P	0.003 ± 0.001	0.16 ± 0.07	6.91 ± 0.95	6.74 ± 0.51	0.024

All units are in mg C m⁻² min⁻¹. SGWP is calculated as 45 times the measured soil CH₄ flux when CH₄ was emitted, and as 203 times soil CH₄ flux when there was uptake (Salt) (Neubauer and Megonigal 2015). Corrected NEP is calculated as the difference between NEP and SGWP.

FIGURES

Figure 1. Change in sawgrass aboveground live biomass over time for each treatment. Points represent the monthly mean ($n=6$ replicates per treatment) $\pm$ 1 SE.

Figure 2. Measured aboveground net primary productivity (ANPP) separated by treatment and year. Letters represent the results of a Tukey's post-hoc analysis performed separately for each year. Points represent the annual mean ($n=6$ replicates per treatment) ± 1 SE.

Figure 3. Live aboveground (AG) and belowground (BG) biomass at the end of the experiment. Aboveground biomass was calculated allometrically, whereas belowground biomass was measured through soil coring down to 30-cm depth. Subscripted letters represent differences among treatments from a Tukey's HSD post-hoc test. Bars represent the mean ($n=6$ replicates per treatment) $\pm$ 1 SE in grams dry weight of material per meter squared. The number at the top of each treatment represents the ratio of aboveground to belowground biomass.

Figure 4. Monthly soil CO₂ efflux over time for each treatment. Points represent the monthly mean ($n=6$ replicates per treatment) $\pm$ 1 SE.

Figure 5. Measured soil methane (CH_4) efflux over the first year of the experiment. Points represent the monthly mean ($n=4$ replicates per treatment) ± 1 SE.

Figure 6. Instantaneous flux of gross ecosystem productivity (a; GEP), ecosystem respiration of CO₂ (b; ER), and net ecosystem productivity (c; NEP). Points represent the monthly mean ($n=4$ replicates per treatment) $\pm$ 1 SE.

SUPPLEMENTAL INFORMATION

Table S1. Source water temperature, salinity, pH, and dissolved constituents added to monoliths designated either “Fresh(+P)” or “Salt(+P)”. Data represent mean ($n=6$ replicates) $\pm$ 1 standard error of temperature, salinity, pH, and dissolved constituents. NO_2^- , NO_3^- , NH_4^+ , SRP, and DOC are in $\mu\text{mol L}^{-1}$. Means were calculated from 1/6/2016 to 12/11/2016 for the freshwater samples and from 1/6/2016 to 5/21/2016 for the saltwater samples. Fresh source water was added to the “Salt(+P)” monoliths starting in June of 2016 to prevent salinity treatment monoliths from becoming hypersaline through evaporation. Fresh and Salt source waters were compared using an independent t-test and * indicates $P < 0.05$.

NO_2^- nitrite, NO_3^- nitrate, NH_4^+ ammonium, SRP soluble reactive phosphorus, DOC dissolved organic carbon

	Fresh	Salt	<i>P</i>
salinity	0.25 $\pm$ 0.03	4.62 $\pm$ 0.19	*
pH	7.72 $\pm$ 0.25	7.77 $\pm$ 0.12	
NO_3^-	0.65 $\pm$ 0.16	1.56 $\pm$ 0.54	
NO_2^-	0.11 $\pm$ 0.05	0.28 $\pm$ 0.13	
NH_4^+	4.14 $\pm$ 1.39	1.21 $\pm$ 0.41	
SRP	0.05 $\pm$ 0.01	0.15 $\pm$ 0.05	
DOC	532.1 $\pm$ 73.8	360.8 $\pm$ 48.6	

Table S2. Surface water temperature, salinity, pH, and dissolved constituents. Data represent mean ($n=6$ replicates) $\pm$ 1 standard error of temperature, salinity, pH, and dissolved porewater constituents averaged across treatments. DOC, TOC, NO_2^- , NO_3^- , NH_4^+ , TN, SRP, and TP are in $\mu\text{mol L}^{-1}$. Letters represent a significant difference in means among treatments from a two-way ANOVA followed by a Tukey's post-hoc test.

Salt		495 ± 5.0	6.73 ± 0.77	276.1 ± 18.8	1792:24:1
Salt+P		503 ± 4.3	6.75 ± 0.57	289.4 ± 13.3	1738:23:1

Data represent mean ($n=6$) ± 1 standard error of C, N, and P sawgrass leaf content for each year. Subscripted letters represent results from a Tukey's HSD test performed separately for each parameter and year. If no letters are present, there were no significant differences between treatments for that parameter and year.

Figure S1. Experimental design of the mesocosm experiment containing the Fresh (F), Fresh + P (F+P), Salt (S), and Salt + P (S+P) treatments. Each monolith was housed within its own individual container within one of six tanks. Each tank contained four monoliths, two receiving P additions and two not receiving any additional P. Even though there was no interaction between each monolith within each tank, a divider was placed between the P addition and no P addition monoliths to prevent any contamination from splashing caused by rainfall (black bar).

CHAPTER III

DECLINES IN PLANT PRODUCTIVITY DRIVE CARBON LOSS FROM COASTAL WETLAND ECOSYSTEMS EXPOSED TO SALTWATER INTRUSION AND SEA- LEVEL RISE

Declines in plant productivity drive carbon loss from coastal wetland ecosystems exposed to saltwater intrusion and sea-level rise

Running head: Saltwater intrusion and ecosystem C cycling

ABSTRACT

Coastal wetlands are among the most productive ecosystems and important reservoirs of carbon (C) on Earth. Accelerated sea level rise (SLR) and saltwater intrusion in coastal wetlands increase salinity and inundation depth with uncertain effects on plant and soil processes that drive C storage. To differentiate soil from plant responses, we exposed peat soil monoliths with and without sawgrass (*Cladium jamaicense*) plants from a brackish marsh to continuous treatments of salinity [elevated (~20 ppt) vs. ambient (~10 ppt)] and inundation levels [submerged vs. exposed (water level 4-cm below soil surface)] for 18 months. We quantified changes in soil biogeochemistry, plant productivity, and whole-ecosystem C flux. We hypothesized that increased inundation depth and salinity would decrease plant productivity and ecosystem respiration (ER). Initial exposure to elevated salinity (within 1 week) increased CO₂ efflux from soils without sawgrass, but elevated salinity had no effect on soil CO₂ efflux from plant-soil monoliths. Elevated salinity had no effect on soil CH₄ efflux, decreased ER by 42% and decreased gross ecosystem productivity by 72%. Control monoliths exposed to ambient salinity had greater net ecosystem productivity (NEP), storing up to 9 times more C than plants and soils exposed to elevated salinity. Increased inundation had no effect on NEP. Decreased plant productivity and soil organic C inputs with saltwater intrusion are likely mechanisms of net declines in soil C storage, which may affect the ability of coastal peat marshes to adapt to rising seas. These results provide experimental evidence for plant-mediated mechanisms for “peat collapse”, a phenomenon observed in the Everglades and other coastal wetland ecosystems.

INTRODUCTION

Coastal wetland ecosystems are important global carbon (C) sinks that are directly threatened by climate change (Kirwan and Megonigal, 2013). With average global sea level rising $\sim 3 \text{ mm yr}^{-1}$ (Ryan and Law, 2005), and recent increases up to 9 mm yr^{-1} in some coastal areas (Wdowinski *et al.*, 2016), saltwater intrusion in low-lying freshwater and brackish coastal wetlands will increase, potentially altering ecosystem C dynamics through effects on plants and soils (Valentine, 2002; Whalen, 2005). Reduced freshwater delivery to some coastal wetlands and increased soil erosion through reduced sediment delivery in others can further exacerbate the impacts of SLR and saltwater intrusion on coastal wetlands (Herbert *et al.*, 2015). As C storage is linked to the provision of many ecosystem services, including CO₂ sequestration, recreational and commercial fisheries, water quality, wildlife habitat, and storm surge protection (Engle, 2011; McLeod *et al.*, 2011), understanding how saltwater intrusion alters C storage in coastal ecosystems is crucial for predicting how these vital services will be affected.

Carbon storage in coastal wetlands is controlled by complex interactions between allochthonous water and material supplies, water residence time and depth, physical soil processes, and the metabolic balance of plant production and organic matter mineralization by soil microbes (Morris *et al.*, 2002; Neubauer, 2013; Weston *et al.*, 2006). In wetland soils, increased salinity and water depth associated with SLR can change geochemical and biological processes, resulting in altered C storage capacity (Herbert *et al.*, 2015). Elevated salinity and duration of salinity exposure can create osmotic stress to microbial communities by suppressing cellular respiration or even lysing cells (Chambers *et al.*, 2011; Wichern *et al.*, 2006). Conversely, exposure to some

ionic constituents of saltwater, particularly sulfate (SO_4^{2-}), can increase overall CO_2 efflux from soils through increased sulfate reduction as salinity increases (Chambers *et al.*, 2011; Weston *et al.*, 2011). Unlike sulfate reduction, elevated salinity usually results in decreased rates of methanogenesis through sulfate-reducing bacteria outcompeting methanogens, given the higher energy yield of sulfate reduction (Capone and Kiene, 1988; Poffenbarger *et al.*, 2011; Weston *et al.*, 2006). Yet low-level saltwater addition has also been shown to stimulate CH_4 production from freshwater marsh soils (Weston *et al.*, 2011), and large CH_4 stocks have been found in saline environments (Wilson *et al.*, 2015). Elevated salinity can produce plant morphological and physiological changes (Larcher, 2003; Rejmankova and Macek, 2008) that affect photosynthetic efficiencies, growth, maintenance, and nutrient uptake (Neubauer, 2013; Pezeshki *et al.*, 1987a; Pezeshki *et al.*, 1987b). Because microbial respiration and plant productivity strongly mediate CO_2 and CH_4 exchange in wetlands, understanding short- and long-term responses to saltwater exposure and increased water depth is critical to understanding soil C storage.

In addition to increasing salinity, SLR can also increase water depth, flood duration, and residence time. In many coastal wetlands influenced by tidal and riverine sediment inputs, increased water depth equates to higher inorganic sedimentation rates and, therefore, higher accretion rates up to a threshold (Morris *et al.*, 2002). In coastal mangrove and marsh ecosystems that receive little sediment input, however, root production has been identified as the primary driver of vertical peat accretion and soil C accumulation (Baustian *et al.*, 2012; McKee, 2011; Nyman *et al.*, 2006). Higher water levels create a diffusive barrier that prevents oxygen and other gases from entering the

soil, affecting plant productivity (Jackson and Colmer, 2005), and suppressing aerobic respiration and overall organic C mineralization, which leads to a reduction in overall soil CO₂ efflux to the atmosphere (Neubauer *et al.*, 2000). Longer water residence time leads to a predominance of anaerobic respiratory pathways, typically allowing methanogens to thrive where sulfate concentrations are low (i.e., low salinity; Poffenbarger *et al.*, 2011), leading to increases in CH₄ efflux (Morse *et al.*, 2012). Increased flooding depth has been shown to decrease plant productivity (Wichern *et al.*, 2006) and gross ecosystem productivity (GEP; Whalen, 2005), usually as a result of decreased leaf area available for gas exchange (Schedlbauer *et al.*, 2010), oxygen stress of roots, and increased production of phytotoxins (Rejmankova and Macek, 2008). However, a resulting decrease in ecosystem respiration (ER) can be greater than the effect on GEP, resulting in increased net ecosystem productivity (NEP; Whalen, 2005).

Coastal peat marshes are especially susceptible to saltwater intrusion and changes in water depth (Herbert *et al.*, 2015; Whittle and Gallego-Sala, 2016), but little is known about how exposure to salinity affects organic matter accumulation and peat stability. In areas with low inorganic sediment input, peatland soils can be highly organic (>65% organic matter) and vulnerable to external drivers, such as freshwater diversion and effects of climate change (Delaune *et al.*, 1994; McVoy *et al.*, 2011). The Everglades is the largest coastal peatland in the United States (>6000 km²; Richardson *et al.*, 2008) and one of the most vulnerable to SLR, as 60% of Everglades National Park (ENP) is at or below 0.9 m in elevation (Pearlstone *et al.*, 2010). Freshwater flow through the Everglades has been greatly reduced by compartmentalization (creation of water storage areas) and overall reduction in water delivery, resulting in less freshwater flow into the

Everglades, leaving the ecosystem highly vulnerable to saltwater intrusion (Light and Dineen, 1994; Saha *et al.*, 2011). The term “peat collapse” has been used to describe a relatively rapid shift in soil C balance, leading to a net loss of organic C and loss of soil elevation, culminating in a conversion of vegetated marsh to open water ponds (Delaune *et al.*, 1994). This process has been documented to varying degrees in different coastal wetlands and has been attributed to changes in microbial processes, increased sulfate reduction, sulfide accumulation, eutrophication from excess nitrogen (N) inputs, inadequate plant production, and vegetation damage from tropical storms, contributing to the instability of inland marshes (Cahoon *et al.*, 2003; Deegan *et al.*, 2012; Delaune *et al.*, 1994; Voss *et al.*, 2013). Areas of peat collapse have been observed in the brackish and saline marsh areas of the coastal Everglades (Fig. 1), yet the mechanisms behind this collapse are not understood (Chambers *et al.*, 2015; Wanless and Vlaswinkel, 2005). Therefore, understanding how factors associated with SLR that exacerbate saltwater intrusion in the coastal Everglades and potentially alter C storage and peat stability is critically important for the future of Everglades coastal wetlands.

Past studies have identified C responses to salinity or water depth in soils (Chambers *et al.*, 2013; Chambers *et al.*, 2011; Marton *et al.*, 2012; Weston *et al.*, 2006; Weston *et al.*, 2011), but fewer have investigated interactions between soil and plant processes in vegetated soil systems (Neubauer, 2013; Neubauer *et al.*, 2000; Weston *et al.*, 2014). The drivers and mechanisms of peat collapse may be different depending on the presence or absence of plants. The interaction between plant production and soil functions play an integral role in the persistence of coastal wetlands, and, therefore, understanding responses of soils, as well as the interaction with plants, to elevated

salinity and water depth is crucial to interpreting these studies and to understanding applicability to coastal peat marsh vulnerability.

To examine the influence of salt exposure and inundation on soil and plant processes driving coastal peat marsh C cycling, we conducted two mesocosm experiments using Everglades brackish marsh monoliths: one experiment examined responses in peat soils without plants to determine soil responses in the absence of plants (“soil-only”); the other evaluated plant and peat soil responses to determine their interaction effect (“plant-soil”). We conducted two separate experiments on different habitats within the marsh because, given the loss of vegetation and formation of open water ponds that is predicted to occur with saltwater intrusion, C and soil biogeochemical cycling will likely be altered after a marsh transitions to an open water pond (Spivak *et al.*, 2017). Within the soil-only experiment, we hypothesized that elevated salinity would increase overall soil CO₂ efflux, with the greatest effect occurring after initial exposure. We predicted that elevated salinity would decrease CH₄ efflux, as sulfate replaced CH₄ as the terminal electron acceptor, while higher water depth would increase CH₄ efflux given more reduced conditions. In the plant-soil experiment, we hypothesized that elevated salinity would decrease GEP while increasing ER and soil CO₂ efflux, leading to decreased NEP and a change in the marsh from a net C sink to a C source. We also hypothesized that higher water depth would decrease soil CO₂ efflux as a result of more reducing conditions, mitigating some of the effects of elevated salinity and dampening the overall loss of C to the atmosphere. When considering the transition from a vegetated to non-vegetated marsh, we predicted that soil CO₂ efflux would decelerate because of a reduction in labile C inputs from vegetation and no active root respiration occurring.

MATERIALS AND METHODS

Soil-only experiment

Study site and experimental facilities. We collected twenty-four peat soil monoliths (25-cm deep $\times$ 28-cm diameter) on 22 July 2014 from a brackish marsh of Shark River Slough (25°13'13.52" N, 80°50'36.70" W) in ENP, a supratidal location about 5-km inland from Florida Bay. The site was dominated by dense sawgrass patches (*Cladium jamaicense*), interspersed with buttonwood (*Conocarpus erectus*) and open water ponds with senescing and dead sawgrass plants. Peat was approximately 1 m deep to a ~0.5 m mineral layer overlying limestone bedrock. The soil total C content within the top 10-cm at this site was 42.6 ± 0.2 % (mean $\pm$ 1 standard error from 5 cores), bulk density was 0.133 ± 0.008 g cm⁻³, 84.5 ± 0.5 % of the soil was organic matter, and water occupied 88.5 ± 0.8 % of the pore space. At the time of collection, ambient porewater salinity was ~9 ppt. Anecdotal evidence suggests this was a freshwater peat marsh in 1952 (Beard *et al.* 1952). We excavated the peat monoliths intact using shovels and placed them into perforated buckets with mesh screen over the perforations that allowed water exchange while minimizing sediment loss (Chambers *et al.*, 2013). Extracted monoliths were dug out slightly larger than the size of the bucket and were shaved down to a uniform size while being placed into the bucket. Monoliths were transported to an outdoor mesocosm facility at ENP's Florida Bay Interagency Science Center (FBISC) in Key Largo, FL.

We used a randomized split-plot experimental design with repeated measurements. The two manipulated factors were salinity (the whole-plot factor with two nested blocks) and inundation (the sub-plot factor), which were both fixed factors. Once

on site, monoliths were carefully immersed in six 250-gallon concrete tanks equipped with an adjustable inflow spigot, a 30-cm tall standpipe to maintain consistent water level, and an outflow drain; three tanks had elevated salinity (20 ppt), while three had ambient salinity (10 ppt). Within each tank, the water depth for a monolith was controlled by setting it on the bottom of the tank (completely submerged) or by setting it on a shelf in the tank that elevated the surface of the monoliths ~4 cm above water surface (exposed). The monoliths were randomly assigned to either an elevated salinity or ambient salinity tank and to either completely submerged or exposed water depth.

Salinity was controlled by mixing water weekly to desired experimental salinity concentrations from four 2,000-gallon head tanks, 2 with freshwater and 2 with saltwater, and the mixture was pumped at a constant flow (36-mL min^{-1}) into each mesocosm tank. Freshwater was collected from a nearby canal and had similar nutrient concentrations to freshwater portions of the Everglades (C-111; $25^{\circ}17'31.74''\text{ N}$, $80^{\circ}27'21.59''\text{ W}$). Saltwater head tanks were equipped with a pump to draw water from adjacent Florida Bay.

The soil monoliths were allowed to acclimate for 3 weeks under ambient salinity (~10 ppt) and completely inundated conditions before treatment manipulation and measurements began. The “exposed” designated monoliths were then raised to ~4-cm above the water surface before the commencement of the two experiments. There were two phases in the experiment: an 8-day “ramp up” period (Aug 20-28, 2014) in which salinity was incrementally raised from ambient (10 ppt) to treatment (20 ppt) salinity, and, immediately following, a 12-week “press” period (Sep to Nov 2014) in which salinity remained elevated. The four treatments were designated as: (1) Amb.Sub, (2)

Amb.Exp, (3) Salt.Sub, (4) Salt.Exp, where the salinity treatment was defined as either ambient (Amb) or elevated (Salt), and the inundation treatment was defined as either completely submerged (Sub) or top 4-cm of soil exposed above the water surface (Exp).

Surface water and soil porewater physicochemistry. Surface water in each tank was collected weekly using a 60-mL syringe and field filtered through 0.7- μ M glass fiber filters (GFF) into acid washed plastic bottles. At the time of collection, temperature ($^{\circ}$ C), salinity (ppt), and pH was measured on samples of freshwater source, saltwater source, and tank surface water using a YSI Model 600 XL (Xylem, Inc., Yellow Springs, OH, USA). Soluble reactive phosphorus (SRP), total dissolved P (TDP), and dissolved inorganic N (DIN) was analyzed at the South Florida Water Management District Water Quality Laboratory on a four-channel Lachat Flow Injection Analyzer 5000 auto-analyzer (Lachat Instruments, Loveland, CO, USA). Sulfate (SO_4^{2-}) was analyzed using an ion chromatograph (Metrohm 881, Riverview, FL, USA). Dissolved organic C (DOC) was analyzed using a Shimadzu TOC-L analyzer (Shimadzu Scientific Instruments, Columbia, MD, USA; Eaton *et al.*, 2005).

Porewater sippers [plastic tubing attached an air stone (4-cm long x 1-cm diameter)] were inserted to 15-cm depth near the middle of each monolith. Porewater was collected weekly using a 60-mL syringe by placing suction on the sipper and evacuating the tubing before collecting a sample. Water was filtered (0.7- μ M GFF) into unused plastic bottles. Porewater was analyzed for temperature, salinity, and pH immediately after collection. Dissolved constituents (SRP, TDP, DOC, DIN, SO_4^{2-}) were analyzed as described above.

CO₂ and CH₄ efflux. Prior to the beginning the experiment, one 10-cm diameter PVC collar was installed 5-cm into the soil of each peat monolith for soil C efflux measurements. During the “ramp up” period of the soil-only experiment, soil CO₂ efflux was measured daily for 120 seconds using a portable infrared gas analyzer (Li-Cor 8100, Lincoln, NE, USA; Chambers *et al.*, 2013). Soil CO₂ efflux was measured weekly during the “press” period.

Methane was measured biweekly on a subset of monoliths during the “press” period using the LI-8100 modified to collect a subset of air for trace gas sampling (Chambers *et al.*, 2013). Four out of the six monoliths for each treatment ($n=16$) were randomly chosen at the beginning of the experiment, and measurements occurred weekly on the same monoliths. The chamber was sealed for 15 min and 25-mL of gas was withdrawn using a 60-mL syringe at both the beginning and end of the 15-min sampling period from a port in-line with the instrument; the gas was sealed in a 20-mL evacuated glass vial and transported back to the lab for analysis. Samples were run on a gas chromatograph (Shimadzu Scientific Instruments GC 8A, Columbia, MD, USA) fitted with a flame ionization detector. Methane flux was calculated as the slope of CH₄ concentration over time.

Plant-soil experiment

Study site and experimental design. We collected 24 plant-soil monoliths on 7 January 2015 from the same site as described above using the same method except that monoliths had sawgrass plants (*C. jamaicense*) as well as soil. On site, areas with ~3 plant culms

per 0.06 m^{-2} were selected for monolith collection. Monoliths were transported to FBISC and allowed to equilibrate at ambient (10 ppt) and inundated conditions for one month. The experimental design was identical to the previous experiment except there was a more gradual “ramp-up” period (three months) in which salinity was raised from ambient (10 ppt) to 20 ppt in the elevated salinity treatments. The second experiment lasted a total of 18 months from February 2015 to July 2016.

Surface water and soil porewater physicochemistry. Surface water and porewater was collected and analyzed monthly using the same methods described above. Sulfide (HS^-) was measured using standard methods (McKee *et al.*, 1988). Soil redox potential was measured monthly using standard techniques (Faulkner *et al.*, 1989). We inserted three platinum-tipped probes to a depth of 5-cm in each monolith and allowed to equilibrate for 30 minutes until measurements were taken.

CO_2 and CH_4 efflux. Prior to the experiment, one 10-cm diameter PVC collar was installed 5-cm into the soil in each monolith to allow for soil C efflux to be measured. Soil CO_2 efflux was measured monthly using the methods described above. Soil CH_4 was measured using the methods described above. During the first year, soil CH_4 was measured monthly, but because of the lack of detectable flux, soil CH_4 efflux measurements were cut to bi-monthly for the last 6 months. Soil CO_2 and CH_4 efflux were not measured in April 2015 because of equipment failure.

Ecosystem CO₂ exchange. Ecosystem CO₂ exchange was measured monthly in the plant-soil experiment with a transparent static chamber (53 L × 38 W × 150 H cm) placed over the monoliths and sealed (Neubauer, 2013; Weston *et al.*, 2014; Wilson *et al.*, 2015). The chamber was equipped with two fans to circulate air. Carbon flux measurements were made in full light near solar noon and in the dark. After sealing the chamber, the system was allowed to equilibrate for 2 mins, then change in CO₂ concentration was recorded every second for 3 mins. During flux measurements, air was pumped from the chamber to a calibrated CO₂/H₂O gas analyzer (LI-COR model LI-840, Lincoln, NE, USA) placed in-line with the chamber. In between light and dark sampling, the chamber top was removed and allowed to equilibrate with atmospheric conditions. NEP was measured in full light, while ecosystem respiration of CO₂ (ER_{CO2}) was measured in the dark immediately after light measurements by covering the chamber with a dark cloth, blocking out all sunlight. GEP was calculated from NEP and ER_{CO2} as:

$$-GEP = -NEP - ER_{CO2} \quad (1)$$

where NEP is instantaneous CO₂ flux (μmol m⁻² s⁻¹) in light and ER_{CO2} is the CO₂ flux in the dark.

Aboveground biomass. Aboveground net primary productivity (ANPP) in the plant-soil experiment was measured non-destructively at bimonthly intervals following methods described in Daoust & Childers (1998). Briefly, each sawgrass culm was tagged and the number of live and dead leaves, shoot height, and culm diameter were measured. Change in aboveground biomass and ANPP were calculated using previously derived allometric relationships between plant height, culm diameter, and biomass (Childers *et al.*, 2006).

Data analyses. Statistical analysis was performed using R (R Core Team 2013). Linear mixed models (Package “nlme”, Pinheiro *et al.* 2017) were used to examine the relationship among physicochemistry of surface and porewater, soil oxidation-reduction potential, C flux, and ANPP and the independent variable of salinity, inundation, and time (fixed factors). To compare between the two experiments, experimental type replaced time in the linear mixed model. Because of the split-plot, nested nature of our experimental design, each salinity tank was set as a block (random factor), while inundation was nested within each block. Normality and homoscedasticity were tested by visually inspecting plotted residuals, and data was log-transformed to increase heteroscedasticity when necessary. The relationship between soil redox potential and temperature was determined using a Pearson product-moment correlation. Culm density was compared between the beginning and end of the experiment for each treatment individually using a paired *t*-test, while culm density among treatments was compared using a *t*-test. Linear regressions were used to determine the relationships between GEP, NEP, ER_{CO2} and sawgrass biomass. Significance for all analyses was determined by an alpha level of 0.05.

RESULTS

Surface and porewater physicochemistry. In the soil-only experiment, surface water was maintained at a salinity of 11.5 ± 0.3 ppt for the 3-week acclimation period. During the 8-day “ramp-up” period, we increased surface water salinity at 1 ppt day^{-1} in the salinity treatment until we reached our target salinity; surface water salinity remained constant for

the duration of the 12-week experiment (Table S1). Porewater salinity closely mirrored surface water salinity for the experimental period (Table 1; Table S1). Surface water temperature over the experiment ranged from 18.0 to 34.3 °C but remained similar between the ambient and elevated salinity tanks (Table S1). Mean pH was more acidic in porewater than in surface water (Table 1; Table S1). Elevated salinity resulted in significantly higher porewater SO_4^{2-} compared to ambient salinity ($F_{(1,4)} = 5.42$, $p=0.028$; Table S2). Full mixed model results for porewater physicochemistry are available in Table S2.

In the plant-soil experiment, surface water temperature ranged from 18.5 to 37.2°C (Table S1). Surface water salinity was maintained at 8 ppt during the 1-month acclimation period. Averaged over the entire experiment, surface water salinity was relatively stable and near experimental targets in both the ambient and elevated salinity treatments, with some variation because of rainfall and evaporation (Table S1). Averaged over the entire experiment, porewater salinities were more stable than surface water salinities (Table 1; Table S1). The elevated salinity treatment resulted in significantly higher porewater SO_4^{2-} ($F_{(1,4)} = 204.97$, $p<0.001$) compared to the ambient salinity treatment (Table S2). Full mixed model results for porewater physicochemistry are available in Table S2. Soil redox potential at 5-cm depth in the plant-soil experiment ranged from +12.3 mV (Amb.Exp, Mar 2015) to +309.4 mV (Amb.Exp, May 2016; Fig. S1). Redox potential varied temporally, with the lowest values occurring in summer 2015, then gradually rising for the duration of the experiment (Fig. S1). Redox was negatively correlated to temperature (Person's $r(343) = -0.198$, $p < 0.001$).

When compared across the same time frame, there were significant differences in all mean porewater constituents between the two experiments ($p < 0.001$; Tables 1, S3). Mean porewater pH, DOC, NH_4^+ , TDN, TDP, and SRP were all significantly higher in the plant-soil experiment, while mean porewater SO_4^{2-} was significantly higher in the soil-only experiment (Table 1).

Soil CO_2 and CH_4 efflux. In the soil-only experiment, soil CO_2 efflux from the “ramp-up” phase was analyzed separately from the “press” phase because the experimental manipulation was different during these two time periods. During the 8-day “ramp-up”, both salinity and inundation had a significant effect on soil CO_2 efflux (Table 2). Elevated salinity and lower water level caused soil CO_2 efflux to increase by 91% compared to the ambient salinity and higher water level monoliths (Fig. 2). During the 12-week “press” phase, soil CO_2 efflux did not differ with either salinity or inundation (Table 2; Fig. 3b). Soil CH_4 efflux was very low, ranging from $-3.7 \text{ nmol CH}_4 \text{ m}^{-2} \text{ s}^{-1}$ (Salt.Sub, Feb 2015) to $20.6 \text{ nmol CH}_4 \text{ m}^{-2} \text{ s}^{-1}$ (Salt.Exp, Feb 2015), with no differences with salinity and inundation (Table 2, Fig. 3a).

In the plant-soil experiment, soil CO_2 efflux varied across the experimental period, with larger efflux during the first half of the experiment and diminished fluxes during the second half with differences between the treatments (Fig. 4b). Soil CO_2 efflux ranged from $-0.08 \text{ } \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ (Amb.Sub, Apr 2016) to $1.86 \text{ } \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ (Salt.Exp, May 2015). Over the entire experiment, inundation led to less soil CO_2 efflux compared to the exposed monoliths ($p = 0.004$), but the effect of salinity was not significant ($p = 0.834$; Tables 2, 3). Soil CH_4 efflux was very low, ranging from -3.6

nmol CH₄ m⁻² s⁻¹ (Amb.Sub, Sep 14, 2014) to 6.2 nmol CH₄ m⁻² s⁻¹ (Salt.Sub, Sep 14, 2014), with no significant differences with either salinity or inundation (Fig. 4a; Table 2).

During the same three months in which soil CO₂ and CH₄ flux measurements were taken (Sep 1 to Dec 1) for the soil-only (2014) and plant-soil (2015) experiments, there was a small, but significant, difference of 2.9°C in surface water temperature ($F_{(1,327)} = 87.71, p < 0.001$). Soil CO₂ efflux was different between the two experiments ($F_{(1,272)} = 14.74, p < 0.001$; Table S3). Specifically, soil CO₂ efflux was higher in the exposed monoliths with plants than compared to those without plants ($F_{(1,272)} = 7.11, p = 0.008$; Tables 5, S3). Soil CH₄ efflux also varied across inundation and experiment, with lower fluxes from the submerged monoliths with plants compared to the submerged monoliths without plants ($F_{(1,226)} = 7.21, p = 0.007$; Tables 5, S3)

Ecosystem exchange. Across the 18-month sampling period during the plant-soil experiment, calculated GEP at solar noon ranged from 0.16 μmol CO₂ m⁻² s⁻¹ (median for Salt.Exp plots, May 2015) to 4.1 μmol CO₂ m⁻² s⁻¹ (median for Amb.Exp plots, Feb 2016, Fig. 5a). Across all treatments, GEP was higher during the second year compared to the first (Fig. 5a), while overall, elevated salinity led to less CO₂ uptake compared to the ambient conditions ($p = 0.003$; Table 3). Ecosystem respiration of CO₂ ranged from 0.19 μmol CO₂ m⁻² s⁻¹ (median rates, Salt.Sub plots, Oct 2015) to 1.3 μmol CO₂ m⁻² s⁻¹ (Amb.Exp, Jun 2016, Fig. 5b). Both salinity and inundation had significant effects on ER_{CO2} ($p < 0.05$; Table 2). With both high and low water levels, ER_{CO2} was decreased by 47% and 37% with elevated salinity, respectively (Table 3). Within both salinity treatments, inundation resulted in significantly less ER_{CO2} (Table 3). ER_{CO2} did not vary

much for all treatments for the entire study period (Fig. 5b). NEP ranged from $-0.37 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ (median for Salt.Exp, Mar 2015) to $4.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ (Amb.Exp, Dec 2015, Fig. 5c). Overall, elevated salinity led to less CO_2 uptake ($p=0.003$), while there was no effect of inundation on NEP ($p=0.308$; Tables 2,3).

Aboveground density and biomass. At ambient salinity, culm density within the plant-soil experiment increased from 2.7 ± 0.4 culms plot^{-1} to 5.2 ± 0.9 culms plot^{-1} over the 18-mo experiment ($t=3.61$, $p<0.01$). At elevated salinity, culm density remained unchanged (2.6 ± 0.5 culms plot^{-1} to 3.2 ± 0.6 culms plot^{-1} ; $t=1.86$, $p=0.09$) over the same period, so that by the end of the experiment, there was a significant difference in culm density between the ambient salinity and elevated salinity monoliths ($t=2.72$, $p=0.01$). There was no change in culm density within the submerged treatment from the beginning to the end of the experiment (2.8 ± 0.3 culms plot^{-1} to 3.8 ± 0.7 culms plot^{-1} ; $t=2.00$, $p=0.07$). Exposed monoliths increased from 2.4 ± 0.2 culms plot^{-1} to 4.8 ± 0.7 culms plot^{-1} over the duration of the experiment ($t=3.44$, $p<0.01$). At the end of the experiment, however, there were no significant differences in culm density between the inundated and exposed monoliths ($t=1.66$, $p=0.11$). Salinity reduced ANPP ($p=0.038$), but inundation had no effect on ANPP ($p=0.199$; Table 2, Fig. 6). GEP was significantly related to biomass in all treatments, whereas GEP was only correlated to ER_{CO_2} in the Amb.Exp treatment (Table 4).

DISCUSSION

Our objective was to understand how specific stressors of SLR and saltwater intrusion (i.e., elevated salinity and increased water depth) would affect coastal wetland

C and soil biogeochemical dynamics and how these processes influence peat collapse. To do this, we compared extracted monoliths from an intact plant-soil marsh to a nearby open-water pond that contained only soil. Soil CO₂ efflux spiked with initial exposure to salinity in the soil-only experiment, but this effect did not persist for the duration of the experiment, while enhanced soil exposure had no effect on soil CO₂ efflux. In the plant-soil experiment, soil CO₂ efflux was not affected by salinity, but was influenced by soil exposure. Elevated salinity, regardless of inundation level, significantly reduced C uptake by the marsh by reducing NEP (Table 3). The decline in NEP was not caused by an increase in soil respiration or ER but rather by a substantial decrease in plant productivity and GEP. Our results are consistent with increasing numbers of studies showing significant changes to ecosystem C cycling in marshes experiencing saltwater intrusion (Herbert *et al.*, 2015; Neubauer, 2013). Below, we examine how elevated salinity and water depth influence coastal wetland C processing from both plant-soil matrices and degraded soils. We then consider the implications C processing may have on coastal wetland survival, given accelerating SLR.

Effects of salinity and inundation on peat soils

Numerous studies have shown varying responses of soil CO₂ efflux with saltwater intrusion into freshwater wetland soils (Chambers *et al.*, 2011; Weston *et al.*, 2011), yet few have tested this response on brackish water wetland soils. Without plants, soil CO₂ efflux significantly increased with initial elevated salinity and soil exposure (Fig. 2). This may be attributed to a combination of enhanced oxidation with exposure and the delivery of more SO₄²⁻ ions associated with elevated salinity, as sulfate reduction has been shown

to become the dominant pathway of organic matter oxidation as salinity increases (Table 1; Weston *et al.*, 2006; Weston *et al.*, 2011). Chambers *et al.* (2011) reported a similar spike in CO₂ efflux after exposing freshwater marsh soils to elevated salinity seawater; this spike in CO₂ efflux also diminished over time. Chambers *et al.* (2011) concluded that this was a result of excess SO₄²⁻ present in seawater because they did not see the same spike in CO₂ efflux when exposing the soils to deionized water mixed with NaCl. Results from this study and that of Chambers *et al.* (2011) are consistent with Edmonds *et al.* (2009), who showed that microbes switch biogeochemical pathways (i.e., from methanogenesis to SO₄²⁻ reduction) and gene expression and regulation over very short times following saltwater exposure. After the one-week “ramp up”, the effect of elevated salinity on increasing CO₂ efflux diminished, resulting in no further differences in CO₂ efflux across treatments (Fig. 3b). We expected to see higher soil CO₂ efflux under conditions of soil exposure, as oxygen can diffuse through the sediments faster in air than in water, allowing for alleviation of electron pressure and higher C mineralization (Wright and Reddy, 2001). However, we saw no effect of inundation on soil CO₂ efflux in the soil-only experiment. Our relatively small exposure height (soil surface 4-cm above water surface) could have kept the soil surface saturated and anoxic via capillary action (Agosta, 1985; Nyman and Delaune, 1991). The short duration of the experiment (3 months in fall/winter) could also have resulted in our missing this response because of seasonal effects (Phillips *et al.*, 2010).

Effects of salinity and inundation on sawgrass peat marshes

Salinity has been shown to lead to both positive and negative feedbacks on soil respiration (Stagg *et al.*, 2017). Elevated salinity can increase soil CO₂ efflux, as seen in the soil-only experiment (see above). However, elevated salinity in our study did not affect soil CO₂ efflux. With plants present, inundation, but not salinity, had a significant effect on soil CO₂ efflux (Table 2). As expected, enhanced soil exposure to the atmosphere led to more CO₂ efflux, likely because of oxygen availability, which enhances microbial respiration (Reddy and DeLaune, 2008). In a similar experimental study, Chambers *et al.* (2013) also found that elevating salinity in mangrove peat soils (16.6 to 32.6 ppt) did not change the rate of soil CO₂ efflux. Because our soils were already brackish in nature, elevating salinity from 10 to 20 ppt likely did not affect microbial processes, especially considering that water for our elevated salinity treatment was sourced from an estuary with high salinity (~38 ppt, Table S1). By using seawater to elevate salinity, we likely changed the microbial structure and function of the soil microbial community to become more salt tolerant (Andronov *et al.*, 2012; Yan *et al.*, 2015), which may explain why ER was unchanged. Soil CH₄ efflux in this experiment was also low and not affected by salinity or inundation (Table 3), which is expected from brackish wetland soils where methanogenesis is low (Wilson *et al.*, 2015). High concentrations of porewater SO₄²⁻ and HS⁻ usually result in high rates of sulfate reduction compared to methanogenesis (Capone and Kiene, 1988). A large proportion of CH₄ flux is lost to the atmosphere through aerenchyma present in macrophytes in wetland ecosystems (Laanbroek, 2010; Whiting and Chanton, 1993), *C. jamaicense* does not have

flow-through aerenchyma (Chabbi *et al.*, 2000) and therefore does not have an enhanced pathway for CH₄ evasion through plants to the atmosphere.

Small increases in salinity can significantly impact gas exchange in wetland plants (Pezeshki *et al.*, 1989). Continuously elevated salinity reduced GEP by 74 and 70% compared to the ambient salinity-inundated and -exposed treatments, respectively (Table 5). Our finding is consistent with previous field and laboratory experiments that show significant reduction in plant productivity given elevated salinity, the potential mechanisms of which are detailed in other studies (Herbert *et al.*, 2015; Neubauer, 2013). Elevated salinity decreased ER_{CO2} by 47 and 37% compared to the ambient salinity-submerged and -exposed conditions, respectively (Table 3). As there was no change in soil CO₂ efflux with elevated salinity, the decrease in ER_{CO2} seen in our experiment can be attributed to decreased leaf respiration. Additionally, ER_{CO2} was relatively stable throughout the entire experiment with very little monthly variation and was not correlated to GEP in most treatments (Fig. 5, Table 4). This runs counter to similar studies that show that GEP and ER_{CO2} are highly correlated and decrease in similar proportions with elevated salinity (Neubauer, 2013; Weston *et al.*, 2014). Greater inundation decreased ER_{CO2}, which was directly tied to a decrease in soil CO₂ efflux (Table 3). Overall, elevated salinity decreased NEP by 86 and 88% compared to ambient salinity with inundated and exposed conditions, respectively (Table 3). Although there were a few months in which NEP was negative (Fig. 4c), indicating the marsh was a net source of CO₂ to the atmosphere, averaged over the entire experimental period, elevated salinity did not lead to a net efflux of CO₂. However, our measurements were taken near solar noon and on sunny days and represent the maximum GEP potential of the vegetation.

Therefore, we performed an exercise to integrate our data over a daily, and subsequently, an annual time frame. We took previously derived light response curves for a brackish *C. jamaicense* marsh (Wilson *et al.*, 2015) and used standard methods to estimate annual flux (Neubauer, 2013; Wilson *et al.*, 2015). Briefly, we took our measurement made in full light for each month and scaled it to 5 different rates and different light levels using the previously derived light response curve for that same month (Wilson *et al.*, 2015). We used temperature and light (PAR) data from a nearby weather tower (MBTS, DBHydro, South Florida Water Management District) to determine the maximum light level for that day. We then used standard equations to estimate daily, monthly, and annual flux (Neubauer, 2013; Wilson *et al.*, 2015).

After daily integration, we found that all treatments were a net source of CO₂ to the atmosphere, with elevated salinity and soil exposure greatly amplifying CO₂ loss (Fig. 7). This was mostly driven by a sharp decline in GEP with elevated salinity, with only a disproportionate decline in ER, leading to larger CO₂ loss. The effect of elevated salinity was largest when the soils were exposed. As the historical sheet flow of water to the southern coastal Everglades has been significantly reduced over the past century (McVoy *et al.*, 2011), greater duration of dry down and soil exposure, coupled with increasing porewater salinity, has likely contributed to significantly altering the flow of CO₂ through the marsh and the atmosphere. Given current restoration efforts to restore more sheet flow to the southern Everglades (Perry, 2004), more water could lead to fewer periods of dry down and lessen the loss of C from brackish water marshes experiencing saltwater intrusion. While elevated salinity accelerates CO₂ loss from the marsh, even under ambient salinity conditions, we found the marsh to be a net source of CO₂ to the

atmosphere. The brackish marsh where we chose to conduct this study had already experienced visual evidence of peat collapse (Fig. 1), and our finding of the marsh as a net source of CO₂ to the atmosphere under ambient conditions may help explain this collapse.

Plant losses mediate C flux and biogeochemistry

Within a single marsh, vegetation cover can vary heterogeneously, and biogeochemical processing can vary depending on the presence of plants (Spivak *et al.*, 2017). We found that the presence of plants led to different soil CO₂ efflux rates with both elevated salinity and water depth. Overall, we saw no effect of elevated salinity on soil CO₂ efflux in either experiment (Table 2). However, compared across experiments with and without plants, effects of elevated salinity and inundation point to the importance of wetland plants in influencing soil respiration. Although these experiments were not conducted in tandem, the experimental conditions were similar, meriting comparison among flux responses (Table S1).

We expected to see higher soil CO₂ efflux under conditions of soil exposure during both experiments, as oxygen can diffuse through the sediments faster in air than in water, allowing for alleviation of electron pressure and enhanced C mineralization (Wright and Reddy, 2001). However, we saw no effect of inundation on soil CO₂ efflux in the soil-only experiment. Our relatively small exposure height (soil surface 4-cm above water surface) could have kept the soil surface saturated and anoxic via capillary action (Agosta, 1985; Nyman and Delaune, 1991). On the contrary, with plants present, soil CO₂ efflux was 3-5 times higher than soil monoliths without plants only when the

soil surface was exposed (Table 5). Although *C. jamaicense* does not use active transport of oxygen to alleviate anoxic root stress, passive transport still occurs (Chabbi *et al.*, 2000). This mechanism of obtaining oxygen, not present in soils without plants, could lead to more oxidized conditions, stimulate aerobic respiration, and therefore lead to the greater CO₂ efflux we observed in monoliths with plants as compared to those without. Roots are another factor that could be causing this discrepancy in soil CO₂ efflux across experiments. Root respiration has been shown to account for anywhere between 22 and 81% of overall soil respiration (Li *et al.*, 2016; Wang *et al.*, 2006). Under inundated conditions, root respiration is likely to be diminished as plants will retain oxygen in order to avoid resorting to alcoholic fermentation, a process that produces ethanol, a plant toxin (Vartapetian and Jackson, 1997). Under exposed conditions, anoxia stress in plants is alleviated, allowing for enhanced root respiration (Pezeshki and DeLaune, 2012).

Global implications of saltwater intrusion on C in coastal wetlands

A number of studies have shown significant changes to ecosystem C cycling in marshes experiencing saltwater intrusion (Herbert *et al.*, 2015; Neubauer, 2013). However, few of these studies focused on coastal peatlands. Our study illustrates how saltwater intrusion alters ecosystem C cycling, resulting in less CO₂ uptake, and how the interaction with greater inundation depth had little influence on aspects of C cycling that we measured. These results indicate that a sustained increase in salinity in brackish coastal marshes, an issue facing coastal wetlands globally, substantially alters C cycling and could disrupt and change ecosystem structure and function. As climate change and increased human alteration of hydrologic cycles continues, instances of wetland

salinization will increase (Herbert *et al.*, 2015). Although the specific responses to increased salinization will vary on a case-by-case basis, depending on frequency and magnitude of exposure, initial soil conditions, hydrologic flow, etc., our results indicated that elevated salinity in coastal wetlands has the potential to dramatically decrease NEP and stimulate CO₂ evasion from the marsh (Fig. 7). Peat soils, and the stabilization of these soils, depend on the input of organic material for their existence. Without this input, destabilization of peat soils could occur, potentially leading to collapse and conversion from a marsh to an open pond habitat (Delaune *et al.*, 1994). In freshwater and brackish marshes, the potential for peat collapse also is affected by the ability of other, more salt-tolerant, plant species to migrate in and stabilize the soil (Donnelly and Bertness, 2001; Langley *et al.*, 2013; Smith, 2009). Saltwater intrusion into coastal wetlands is occurring worldwide (Herbert *et al.*, 2015), and the rate will only increase with accelerated SLR. Elevated salinity is usually coupled with other pressures facing coastal wetlands, such as drought (Ardon *et al.*, 2013), altered hydrologic regimes (Green *et al.*, 2017), eutrophication (Deegan *et al.*, 2012), and anthropogenic barriers to migration (Enwright *et al.*, 2016), all potentially interacting to influence the ability of these ecosystems to store globally relevant amounts of organic C.

Our findings showed that saltwater intrusion affected plant C cycling much more than soil C cycling in brackish coastal peatlands, yet little is known about wetland plant tolerance ranges and adaptability. Additional research is needed to investigate these tolerance ranges to accurately quantify coastal marsh vulnerability to peat collapse. Specific areas of focus should also include investigating saltwater intrusion effects into freshwater marshes, measuring *in situ* field responses, and investigating how saltwater

intrusion interacts with other climate drivers, such as drought, to potentially influence peat collapse. With many large-scale coastal restoration plans currently being implemented or in development (US Government Accountability Office, 2007; National Academies of Sciences, Engineering, and Medicine, 2016), understanding how current climate change stressors will affect coastal wetlands is essential.

ACKNOWLEDGEMENTS

Funding for research was supported by Florida Sea Grant R/C-S-56, including cooperative agreements with the South Florida Water Management District, the Everglades Foundation, and Everglades National Park. Additional funding was provided through the National Science Foundation's Florida Coastal Everglades Long Term Ecological Research Program (DEB-1237517). We thank Shawn Abrahams, Laura Bauman, Kristina Morales, and Ryan Stolee for help in the field. Viviana Mazzei and Fred Sklar provided valuable feedback on early drafts of this manuscript. We also are grateful to two anonymous reviewers who also provided valuable feedback that greatly improved this manuscript. Benjamin Wilson was supported by a Florida International University Teaching Assistantship, Florida Sea Grant, FCE LTER, and FIU Dissertation Year Fellowship. This is contribution xxxx of the Southeast Environmental Research Center.

TABLES

Table 1. Porewater salinity, pH, redox, and dissolved constituents for the soil-only experiment. Data represents mean $\pm$ 1 SE ($n = 6$ replicates); see linear mixed model results (**Table S2**) for significant differences between the two experiments. DOC, NH_4^+ , TDN, and SO_4^{2-} are in mg L^{-1} , HS^- is in mM, TDP and SRP are $\mu\text{M L}^{-1}$, and redox potential is in mV. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

FIGURES

Figure 1. Photographs taken in March 2015 in the brackish water portion of Everglades National Park showing (A) a group of sawgrass culms forming a “pedestal” and (B) a close up of the culms and exposed roots. The delineation between the bottom of the culms and the exposed roots indicates that the surface of the soil has collapsed about 30 cm (distance from bottom of the culm to current soil surface) over an unknown period of time.

Figure 2. Daily soil CO₂ efflux during the 8-day “ramp-up” period of the soil-only experiment in which salinity was raised by ~1 ppt every day in the elevated salinity monoliths from an ambient salinity of 10 to an elevated salinity of 20 ppt. Salinity in the ambient salinity tanks remained relatively constant during this same period. Points represent the mean ($n = 6$ replicates) ± 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

Figure 3. Soil CH₄ ($n = 4$ replicates) and CO₂ efflux ($n = 6$ replicates) over time for the soil-only experiment. Points represent means ± 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed

Figure 4. Soil CH_4 ($n = 4$ replicates) and CO_2 efflux ($n = 6$ replicates) over time for the plant-soil experiment. Points represent mean ± 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

Figure 5. Monthly instantaneous gross ecosystem productivity (GEP) (a), ecosystem respiration of CO_2 (ER_{CO_2}) (b), and net ecosystem productivity (NEP) (c) in micromoles of CO_2 per meter squared per second over the experimental period for plant-soil experiment. A negative value indicates a flux of CO_2 from the marsh to the atmosphere. Points represent means ($n = 6$ replicates) ± 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

Figure 6. Mean ($n = 6$) $\pm$ 1 standard error of *Cladium jamaicense* (sawgrass) aboveground net primary productivity (ANPP) across the four treatments. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

Figure 7. Schematic of estimated ecosystem C cycling for net ecosystem productivity (NEP), gross ecosystem productivity (GEP), ecosystem respiration of CO_2 (ER_{CO_2}), and soil CO_2 efflux from the plant-soil experiment and how it changes with elevated salinity and/or water depth. Arrows pointing down indicate C entering the marsh, while upward pointing arrows indicate C leaving the marsh to the atmosphere. Values represent mean $(n = 6) \pm 1$ SE flux over the experimental timeframe in $g\ C\ m^{-2}\ y^{-1}$, and the width of the arrows is scaled to the overall flux. Annual flux was calculated using established methods and previously derived light response curves for a *C. jamaicense* brackish water marsh (Neubauer, 2013; Wilson *et al.*, 2015). Amb = Ambient salinity (10 ppt), Salt = Elevated salinity (20 ppt), Exp = Soil surface exposed 4-cm, Sub = Soil surface submerged.

SUPPLEMENTAL INFORMATION

Table S1. Temperature, salinity, pH, and dissolved surface water constituents averaged across all monoliths and the experimental duration for both the soil-only and plant-soil experiments ($n=6$). DOC, NH_4^+ , TDN, and SO_4^{2-} are in mg L^{-1} , HS^- is in mM, and TDP and SRP are $\mu\text{M L}^{-1}$. Error is given as ± 1 standard error

CHAPTER IV

SALTWATER INTRUSION AND DROUGHT DRIVE PEAT COLLAPSE IN A
COASTAL PEATLAND

Saltwater intrusion and drought drive peat collapse in a coastal peatland

ABSTRACT

Climate change threatens globally important carbon stores found in coastal peatlands. Sea level rise and drought intensify saltwater intrusion which elevates salinity and triggers biogeochemical changes that affect wetland carbon storage. However, little work has been done investigating the combined effects of elevated salinity and drought in coastal peatlands. Here, we combined long-term mesocosm experiments and *in situ* field measurements in brackish peatlands to examine the impact of elevated salinity and drought on carbon loss in the Florida Everglades. In our mesocosm experiment, elevated salinity reduced gross ecosystem productivity and belowground root growth, while drought stimulated organic matter mineralization and carbon dioxide loss from the marsh. Soil elevation declined ~2.9 cm in one year under brackish water conditions and by ~4.4 cm when elevated salinity was coupled with drought. Results from our field research revealed seasonal dry-down patterns which led to increased porewater salinity concentration. We suggest that saltwater intrusion initially destabilizes peat soils by reducing organic matter inputs and that seasonal dry-down exacerbates peat collapse.

MAIN

Although peatlands occupy only ~3% of the Earth's surface, they store 15-30% of the world's soil carbon (C) as peat¹. In most peatlands, hydrology drives the flow of C through the ecosystem². Under waterlogged conditions, production outpaces decomposition and C accumulates in soils over millennia. However, a shift in hydrology towards drier conditions, caused by either drought or drainage, can cause extensive vegetation dieback³ and large amounts of stored C to be released to the atmosphere

through enhanced decomposition and can shift the ecosystem from a net C sink to a C source⁴⁻⁶. As stored C effluxes to the atmosphere, degradation of the soil structure can lead to a loss of soil elevation and even a sudden (within a year) collapse of the peat⁷. Although the effects of drought on temperate inland peat soil C have been well studied^{4-6,8}, less is known about coastal peatlands^{9,10}.

The Everglades is the largest subtropical peatland in the world and has accumulated peat soils for the past ~5,000 years¹¹. However, modification and compartmentalization of the landscape in the early to mid-1900s shifted water flows away from the southern coastal Everglades, leaving the area vulnerable not only to drought but also to more saltwater intrusion. Saltwater intrusion into coastal wetlands has been shown to strongly change ecosystem C cycling¹²⁻¹⁷. In coastal peatlands, elevated salinity can lead to decreased plant production and gross ecosystem productivity^{18,19}, which in turn decreases organic matter inputs to the soil through declines in root productivity and biomass²⁰, switches the marsh from an annual net C sink to a net C source^{18,19}, and destabilizes peat, leaving it vulnerable to collapse^{21,22}. Peat collapse has been observed in numerous coastal peatlands^{7,21,23}, including the Everglades (Fig. 1). In mangrove systems, peat collapse has been attributed to tree death following hurricanes⁷. In inland marshes, saltwater intrusion is hypothesized to be the driving force behind peat collapse^{18,19,23,24}; however, it is unclear how saltwater intrusion interacts with seasonal hydrology and drought to influence peat collapse.

Previous work has shown that elevated salinity pulses in a brackish peatland did not affect net ecosystem productivity (NEP) when water covered the soil surface; however, when water fell below the soil surface, as in periods of prolonged drought,

elevated salinity enhanced CO₂ loss from the peatland¹⁹. We conducted an experiment to mimic this coupled saltwater intrusion and drought event in a controlled mesocosm setting to determine how salinity and drought interact to affect the net ecosystem C balance (NECB). We harvested plant-peat soil monoliths from a brackish marsh in Everglades National Park, FL, USA and conducted a year-long mesocosm experiment in which monoliths were subjected to either ambient (10 ppt) or elevated (20 ppt) salinity coupled with a drought treatment (continually inundated or seasonal dry-down; Supplementary Table S1). We measured changes in the NECB which included measurements of CO₂ gas exchange, aboveground and root productivity, root and litter decomposition, and soil elevation change.

The balance between productivity and decomposition controls peat accretion and stability in peatlands that do not have an external supply of sediments²⁵⁻²⁷. Elevated salinity in coastal wetlands can significantly influence soil C inputs by stressing vegetation and decreasing productivity^{15,28}. We found that elevated salinity reduced GEP ($P=0.064$) and aboveground biomass ($P=0.001$) in both inundated and exposed monoliths (Table S2). A reduction in GEP with elevated salinity subsequently led to a significant

reduction in root production of $83 \pm 38\%$ and $85 \pm 24\%$ in the submerged and drought treatments, respectively (Table 1). Root growth and aboveground biomass turnover are the dominant forms of organic matter inputs into coastal peat marshes and contribute the most to vertical accretion²⁷. A decline in these organic matter sources can lead to reduced soil accretion rates and compromise the integrity of peat soils^{7,18}. Delaune et al. (1994) hypothesized that peat collapse in a brackish Louisiana marsh was caused by the loss of live roots and their turgor pressure when exposed to elevated salinity; as roots lose turgor pressure, large air spaces within the roots may collapse.

Table 1. Net ecosystem carbon balance of a brackish water marsh.

Treatment	NEP	GEP	ER_{CO2}	Soil CO₂	ANPP	Root ingrowth	Root Decomp	Leaf Decomp
Amb.Sub	-136 ± 70	585 ± 115	-721 ± 25	-161 ± 23	265 ± 36	94 ± 22	-80 ± 6	-38 ± 3

Salt.Sub	-322 ± 41	279 ± 55	-602 ± 28	-251 ± 80	189 ± 34	16 ± 8	-52 ± 5	-33 ± 2
Salt.Exp	-633 ± 67	298 ± 58	-931 ± 77	-414 ± 73	247 ± 42	15 ± 5	-65 ± 8	-20 ± 1

Mean ± 1 SE of the net annual ecosystem carbon (C) balance ($\text{g C m}^{-2} \text{ yr}^{-1}$) for a brackish water marsh. A positive number indicates an input of C to the marsh, while a negative number indicates a net output of C from the marsh. Statistical information regarding the influence of elevated salinity, drought, and their combined effects can be found in Table S2. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

$n=4$ for NEP, GEP, ER_{CO2}; $n=6$ for Soil CO₂, ANPP, Root ingrowth, Root Decomp, and Leaf Decomp.

NEP net ecosystem productivity, GEP gross ecosystem productivity, ER_{CO2} ecosystem respiration of CO₂, ANPP aboveground net primary productivity, Decomp decomposition

Soil CO₂ efflux responded differently to elevated salinity over short- and long-terms (Supplemental Fig. S1). Two weeks after raising salinity from ~10 to 15 ppt, there was a significant spike in soil CO₂ efflux from the elevated salinity treatments ($P=0.014$). However, this response diminished as salinity was raised from ~15 to 20 ppt with no overall difference in soil CO₂ efflux with elevated salinity for the duration of the experiment (Table 1, $P=0.509$). Results documenting changes in wetland organic matter mineralization with saltwater intrusion have been mixed, with some studies showing long-term acceleration¹³, short-term acceleration²⁹, and deceleration¹⁵ (this study), though the effect is dependent on the salinity concentration and duration of exposure. With exposure to a wide range of salinities, A recent study found that there are thresholds for greenhouse gas production in tidal freshwater wetlands, with moderate amounts of elevated salinity (5-7.5 ppt) stimulating soil CO₂ efflux and higher concentrations (>15 ppt) reducing it³⁰.

Drought, and the subsequent dry-down of water below the soil surface, has been shown to have strong effects on ecosystem C cycling in wetlands as soil oxidation accelerates organic matter breakdown and soil CO₂ efflux to the atmosphere⁵. We found that drought strongly stimulated soil CO₂ efflux ($P=0.017$), but, contrary to our expectations, drought did not affect root breakdown in the top 0-7.5-cm of the soil column ($F_{(1,19)}=0.28$, $P = 0.599$) and slowed root breakdown in the 7.5-15-cm depth range ($F_{(1,19)}=7.65$, $P = 0.012$). This could potentially be a result of changes in peat chemistry during short-term drought conditions. In *Sphagnum* peatlands, the build-up of phenolics in the soil during short-term drought can inhibit soil CO₂ efflux and preserve stored C⁶. Another possible factor is that the amount of surface area exposed to oxygen

was likely different at the soil surface compared to roots buried in the soil. Although water fell below the lowest depth of the roots, residual water within the rooting zone could have kept oxygen levels low^{31,32}. Drought-induced stimulation of soil CO₂ efflux (~194 g C m⁻² yr⁻¹) was much greater than the decline in overall root (no change) and leaf litter (~12 g C m⁻² yr⁻¹) decomposition, indicating that decomposition is not a significant factor driving C loss from the ecosystem (Table 1).

Combined, elevated salinity and drought treatments shifted NEP from a small to large CO₂ source compared to the control monoliths ($P < 0.001$; Table 1). This result was expected, given the physiological salt stress to vegetation³³ and strong soil oxidation under drought⁴. Even under ambient salinity and completely inundated conditions, the brackish marsh in our study was also a net source of C to the atmosphere (Table 1), supporting other studies that found this same conclusion^{18,19}. This may help explain why peat collapse is already being observed in brackish wetlands of the Everglades (Fig. 1). As marshes transition from freshwater to brackish, a decline in GEP leads to a subsequent decline in organic matter inputs and shifts the marsh from a net CO₂ sink to source¹⁹.

IMPLICATIONS FOR PEAT COLLAPSE

Although many coastal wetlands around the world are experiencing ecosystem alterations as the result of changing climate conditions and accelerated SLR³⁴, the rate of ecosystem change and peat collapse observed in the coastal Everglades is unprecedented²³. While we found that both root and litter decomposition slowed with elevated salinity, the overall impact of decomposition on the NECB was minimal compared to the reduction in GEP and organic matter inputs (Table 1). Although soil

bulk density in our study was unaffected by elevated salinity, soil organic matter, C, and N content all declined (Table S4). Under inundated conditions, we measured a substantial amount of soil elevation loss (~ 3.0 cm) with elevated salinity over only a one-year period (Fig. 2). We attribute this elevation loss to the sharp reduction in organic matter inputs with elevated salinity and a net release of CO_2 to the atmosphere. To put this in perspective, coastal marshes accrete slowly over time, usually at or near the same pace as SLR (~ 2 to 10 mm yr^{-1})³⁴⁻³⁸. The peat marshes within the interior Everglades, those which do not receive sedimentation from tidal flushing, have been accreting even slower (~ 0.5 to 2 mm yr^{-1})^{39,40}.

Surprisingly, even under ambient salinity and inundated conditions, we saw a ~ 2.9 cm soil elevation loss over the same period, indicating that the mechanisms that drive peat collapse in the coastal Everglades begin before the marsh fully transitions to brackish conditions (~ 10 ppt). Soil elevation loss under brackish conditions (~ 10 ppt) is further supported in a related mesocosm experiment with freshwater sawgrass-peat monoliths that measured a ~ 2.8 cm decrease in soil elevation after one year of exposure to elevated salinity of ~ 9 ppt (Fig. 3)²⁴. In the same study, Wilson et al. (*in prep*) saw that, although NEP was unaffected by elevated salinity, there was a decrease in the quantity of live roots in the soil, the same result found in this study. Therefore, a decrease in root production and/or an increase in root mortality is one of the primary mechanisms causing peat collapse.

Figure 2. Soil elevation change relative to the elevation at the start of the experiment. Also plotted is water depth relative to the soil surface (blue line). Points represent mean ($n=6$) $\pm$ 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

Figure 3. Soil elevation change relative to the elevation at the start of two separate experiments. The data plotted come from this experiment (filled symbols) and from a similar mesocosm experiment on freshwater sawgrass peat monoliths (open symbols)²⁴. All treatments were not subjected to drought and were completely inundated for the entire experimental period. Points represent mean ($n=6$) $\pm$ 1 SE. BW = brackish water, FW = freshwater, ppt = parts per thousand salinity.

Peat collapse in the coastal Everglades is not only a function of elevated salinity, but appears to be accelerated by seasonal dry-down. Surface water dry-down during the drought period in our experiment accelerated peat collapse; we measured 3 to 4 cm of peat collapse from this brackish water marsh over the course of only one year, with most of the collapse occurring during the onset of dry-down (Fig. 1). It is important to note that, although we only continued to measure elevation change for two months after water was brought back above the soil surface in the drought treatments, the elevation lost during drought did not return. When we conducted this experiment, we mimicked our drought water level regime based on field data from 2015 when the region was experiencing “exceptional” drought. We thought water falling 20-cm below the soil surface was not common and represented an anomalous year. However, when we looked at long-term water level data near the brackish water site where we collected our monoliths (EDEN gauge NP6, USGS), dating back to 2001, dry-down occurred every year, to an average depth of 29.7 cm, and an average duration of 3.9 months (Fig. 4). Therefore, although we expected drought to strongly impact the NECB and elevation, we did not expect that our “drought” treatment was a near-annual occurrence for this marsh.

Further alarming is how seasonal dry-down caused porewater salinity within the soil to increase in a step-wise function at the brackish water site. Three years of monthly ambient porewater salinity from the site shows strong change-points (Fig. 5). Every instance in which water fell below the soil surface coincided with a spike in salinity. This is likely caused by strong groundwater upwelling of brackish water when surface water disappears^{19,41,42}. Additionally, porewater salinity at the marsh stayed elevated during wet periods despite much lower salinity in the surface water, and when the next dry-down

event occurred, porewater salinity spiked (Fig. 5). Because these dry-down events occur annually in these brackish marshes of the Everglades, it is likely that porewater salinity in these marshes will continue to rise, leading to further reductions in the NECB and organic matter inputs, further driving peat collapse.

Figure 4. Historical water level from a brackish water site in the Everglades. (a) Weekly mean ($n=7$) $\pm$ 1 SD water level at the brackish water site relative to the soil surface from 2001 to 2017. (b) Daily water level at the brackish water site from 2001 to 2017. The dashed line represents the soil surface, while the blue line represents either the water level during our one year mesocosm experiment (a) or the minimum water level in our drought experiment (-20 cm; b). Water level data comes from the USGS EDEN gauge NP6.

Figure 5. Ambient porewater and surface water salinity at the brackish water marsh. Mean ($n=6$) $\pm$ 1 SE of monthly porewater (PW) and surface water (SW) salinity (ppt) and daily water depth relative to the soil surface from the brackish water site within the +ambient-water plots¹⁹. Soil surface is plotted as the 0-cm water mark (dashed line) to show its relation to water depth. Solid black lines show the results of a piecewise regression with relevant change-points for PW salinity.

Historical water management practices in the Everglades have significantly altered the water balance and hydroperiod of southern, coastal wetlands by diverting upstream freshwater flows into Biscayne Bay and the Gulf of Mexico, thereby starving southern marshes of freshwater^{11,43,44}. Because seasonal dry-down can accelerate peat collapse (Fig. 2), the restoration of flow regimes to the coastal Everglades has the potential to mitigate peat collapse. Increased water flows can mitigate peat collapse in two ways. First, enhanced freshwater delivery to coastal areas recharges aquifers and creates a stronger freshwater head that helps hold back saltwater intrusion^{42,45}. Second, longer periods of inundation, even with brackish water, can prevent strong, seasonal dry-

down events from occurring⁴⁶. This would greatly reduce groundwater intrusion of marine water into the coastal marshes (Fig. 5) and prevent the acceleration of peat collapse. While it is unlikely that these marshes will ever recover to pre-collapsed conditions in the near future, enhanced water delivery has the potential to slow down collapse and allow for the recruitment and establishment of mangroves that help stabilize the soil⁴⁷. However, given accelerating SLR and delays in the implementation of Comprehensive Everglades Restoration Plan projects⁴⁸, further collapse of peat marshes within the coastal Everglades can be expected. Understanding the drivers and mechanisms behind this collapse is urgently needed to inform management practices aimed at preventing peat collapse and the transformation of marsh habitat to open water ponds in the Everglades and other coastal peatlands^{7,21,49}.

ACKNOWLEDGEMENTS

Funding for research was supported by a National Science Foundation Doctoral Dissertation Improvement Grant (DEB- 1701763). Additional funding came from Florida Sea Grant R/C-S-56, including cooperative agreements with the South Florida Water Management District, the Everglades Foundation, and Everglades National Park, and the National Science Foundation's Florida Coastal Everglades Long Term Ecological Research Program (DEB-1237517). We thank Luran Bauman and Ryan Stolee for help in the field. Benjamin Wilson was supported by a Florida International University Teaching Assistantship, Florida Sea Grant, FCE LTER, and FIU Dissertation Year Fellowship. This is contribution xxxx of the Southeast Environmental Research Center.

SUPPLEMENTAL INFORMATION

Figure S1. Soil CO₂ efflux and water level relative to the soil surface plotted over time. Points represent mean ($n=6$) $\pm$ 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed. Also plotted is water depth (blue line) relative to the soil surface (black line).

Figure S2. Monthly instantaneous gross ecosystem productivity (GEP) (a), ecosystem respiration of CO₂ (ER_{CO2}) (b), and net ecosystem productivity (NEP) (c) in micromoles of CO₂ per meter squared per second over the experimental period. A negative value indicates a flux of CO₂ from the marsh to the atmosphere. Also plotted is water depth (blue line) relative to the soil surface (black line). Points represent mean ($n=4$) $\pm$ 1 SE. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

Figure S3. Monthly modeled gross ecosystem productivity (GEP) (a), ecosystem respiration of CO₂ (ER_{CO2}) (b), and net ecosystem productivity (NEP) (c) in g of C per meter squared per month over the experimental period. Fluxes were modeled from instantaneous flux based on empirical relationships between GEP and light and ER_{CO2} and temperature (*See Supplemental Methods*). A negative value indicates a flux of CO₂ from the marsh to the atmosphere. Also plotted is water depth (blue line) relative to the soil surface (black line). Points represent mean ($n=4$) $\pm$ 1 SD. Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

Table S1. Timeline of water level for the control and drought treatment meant to mimic the water level during the 2015 drought at the brackish water marsh where the soil monoliths were collected. Salinity in the ambient salinity monoliths remained at ~10 ppt for the duration of the experiment, while the elevated salinity monoliths were raised to ~15 ppt in Oct 2016 and ~20 ppt in Nov 2016 and remained at this level for the duration of the experiment.

Date	Control water level	Drought water level
Sep 2016	Submerged	Submerged
Oct 2016	Submerged	Submerged
Nov 2016	Submerged	Submerged
Dec 2016	Submerged	Submerged
Jan 2017	Submerged	At Soil Surface
Feb 2017	Submerged	-10 cm
Mar 2017	Submerged	-20 cm
Apr 2017	Submerged	-20 cm
May 2017	Submerged	-20 cm
Jun 2017	Submerged	-20 cm
Jul 2017	Submerged	-10 cm
Aug 2017	Submerged	Submerged
Sep 2017	Submerged	Submerged

Table S2. Full statistical results for the linear mixed model run with time as an independent variable for C flux, change in biomass, and change in elevation. Interpreted results are in bold. Data presented as F (numerator degrees of freedom, denominator degrees of freedom) = F value, P = P value.

GEP gross ecosystem productivity, ER_{CO_2} ecosystem respiration of CO_2 , NEP net ecosystem productivity, $ANPP$ aboveground net primary productivity.

Table S3. Instantaneous CO₂ flux rates taken near solar noon. Values represent the mean ($\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$) $\pm$ 1 SE for soil CO₂, gross ecosystem productivity (GEP), ecosystem respiration of CO₂ (ER_{CO2}), and net ecosystem productivity (NEP). A negative NEP indicates overall CO₂ release from the marsh to the atmosphere. Flux rates for each parameter is plotted for three time periods: Overall (Sep 2016 – Sep 2017), Inundated (Sep 2016 – Jan 2017, Aug – Sep 2017), and Drought (Feb – Jul 2017). See mixed model results (Table S2) for significant differences.

Amb = Ambient salinity, Salt = Elevated Salinity, Sub = Submerged, Exp = Exposed.

		Amb.Sub	Amb.Exp	Salt.Sub	Salt.Exp
Soil CO₂	Overall	0.42 $\pm$ 0.06	1.02 $\pm$ 0.17	0.66 $\pm$ 0.21	1.09 $\pm$ 0.19
	Inundated	0.38 $\pm$ 0.12	0.59 $\pm$ 0.11	0.89 $\pm$ 0.14	0.89 $\pm$ 0.33

Supplementary Methods

Study site and experimental facilities. Twenty-four peat soil monoliths (25-cm deep x 28-cm diameter) were collected on 3 August 2016 from an oligohaline-mesohaline marsh within Shark River Slough (25°13'13.52" N, 80°50'36.70" W) of Everglades National Park (ENP), FL, USA. The site was located about 5 km inland from Florida Bay and was supratidal. The site was dominated by dense sawgrass patches (*Cladium jamaicense*) interspersed with buttonwood (*Conocarpus erectus*) and open water ponds with senescing and dead sawgrass plants (Fig. 1). Peat was approximately 1 m depth to a ~0.5 m mineral layer overlying limestone bedrock. The soil C content within the top 10-cm at this site was 42.6 ± 0.2 % (mean $\pm$ 1 standard error), bulk density was 0.133 ± 0.008 g cm⁻³, 84.5 ± 0.5 % of the soil was organic matter, and water occupied 88.5 ± 0.8 % of the pore space¹. At the time of collection, ambient porewater salinity was ~12 ppt. On site, areas with ~3 plant culms per 0.06 m⁻² were selected for monolith collection. We extracted the peat monoliths intact using shovels and placed them into perforated buckets with mesh screen over the perforations that allowed water exchange while minimizing sediment loss². Extracted monoliths were dug out slightly larger than the size of the bucket and were shaved down to a uniform size while being placed into the bucket. Monoliths were transported to an outdoor mesocosm facility at ENP's Florida Bay Interagency Science Center (FBISC) in Key Largo, FL.

We used a randomized split-plot experimental design with repeated measurements. The two manipulated factors were salinity (the whole-plot factor) and inundation (the sub-plot factor), which were both fixed factors. Once on site, monoliths were carefully immersed in six 250-gallon concrete tanks equipped with an adjustable

inflow spigot, a 30-cm tall standpipe to maintain consistent water level, and an outflow drain; three tanks had elevated salinity (20 ppt), while three had ambient salinity (10 ppt). Within each tank, the water depth for a monolith was controlled by setting it on the bottom of the tank (completely submerged) or by setting it on a shelf in the tank that elevated it to variable depths determined by the experimental timeframe (Table S1). The monoliths were randomly assigned to either an elevated salinity or ambient salinity tank and to either completely submerged or drought-associated water depth.

Salinity was controlled by mixing water weekly to desired experimental salinity concentrations from four 2,000-gallon head tanks, 2 with freshwater and 2 with saltwater, and was pumped at a constant flow (36-ml min^{-1}) into each mesocosm tank. Freshwater was collected from a nearby canal and had similar nutrient concentrations found in freshwater portions of the Everglades (C-111; $25^{\circ}17'31.74''$ N, $80^{\circ}27'21.59''$ W). Saltwater head tanks were equipped with a pump to draw water from adjacent Florida Bay.

The monoliths were allowed to acclimate for 74 days under ambient salinity and completely inundated conditions before treatment manipulation and measurements began. At the commencement of the experiment, salinity was gradually raised from 10 to 20 ppt in the elevated salinity tanks over a 2-week period and maintained at 20 ppt for the remainder of the experiment. The “drought” designated monoliths followed a scheduled regimen in which water level relative to the soil surface was manipulated (Table S1). The drought manipulation was designed to mimic water levels found at the monolith collection site during a drought year³. One week prior to each monthly sampling regime, the “drought” monoliths were raised or lowered to the corresponding height for that

month (Table S1). The monoliths remained at that level until the next water level change. The four treatments were designated as: (1) Amb.Sub, (2) Amb.Exp, (3) Salt.Sub, (4) Salt.Exp, where the salinity treatment was defined as either ambient (Amb) (10 ppt) or elevated (Salt) (20 ppt), and the inundation treatment was defined as either completely submerged (Sub) (water 5 cm above soil) or subject to the soil surface being exposed because of drought (Exp) (water 20 cm below soil).

Soil CO₂ efflux. Prior to the beginning the experiment, one 10-cm diameter PVC collar was installed 5-cm into the soil of each peat monolith for soil CO₂ efflux measurements. Soil CO₂ efflux was measured monthly for 120 seconds during the daytime on all 24 monoliths using a portable infrared gas analyzer (Li-Cor 8100, Lincoln, NE, USA)².

Ecosystem CO₂ exchange. Ecosystem CO₂ exchange was measured monthly with a transparent static chamber (53 L x 38 W x 150 H cm) placed over the monoliths and sealed⁴⁻⁶. The chamber was equipped with two fans to circulate air. Carbon flux measurements were made in full light near solar noon and in the dark. After sealing the chamber, the system was allowed to equilibrate for 2 mins, after which change in CO₂ concentration was recorded every second for 3 mins. During flux measurements, air was pumped from the chamber to a calibrated CO₂/H₂O gas analyzer (LI-COR model LI-840, Lincoln, NE, USA) placed in-line with the chamber. In between light and dark sampling, the chamber top was removed, allowing the chamber to equilibrate with atmospheric conditions. NEP was measured in full light, while ecosystem respiration of CO₂ (ER_{CO2})

was measured in the dark immediately after light measurements by covering the chamber with a dark cloth, blocking out all sunlight. GEP was calculated from NEP and ER_{CO_2} as:

$$-GEP = -NEP - ER_{CO_2} \quad (1)$$

where NEP is instantaneous CO_2 flux ($\mu\text{mol m}^{-2} \text{s}^{-1}$) in light and ER_{CO_2} is the CO_2 flux in the dark. Daily integrated CO_2 flux was modeled using previously established methods¹.

Aboveground vegetation. Aboveground net primary productivity (ANPP) was measured non-destructively at bimonthly intervals following standard methods⁷. Briefly, each sawgrass culm was tagged and the number of live and dead leaves, shoot height, and culm diameter measured. Change in ANPP was calculated using previously derived allometric relationships between plant height, culm diameter, and biomass⁸.

Organic matter inputs and breakdown. Root growth was measured using the ingrowth core method⁹. One 1-mm nylon mesh bag (15-cm long, 3-cm diameter) filled with commercially available peat moss was inserted into the middle of each monolith after a core of the same size and depth was removed and was retrieved after one year. Living roots, those which floated to the surface when submerged in water, were separated from the peat material using a sieve and running water, dried at 60°C for one week, and weighed for biomass.

Root breakdown was measured on sawgrass roots. Sawgrass roots were collected at the same site as the monolith collection, washed, and dried at 60°C until weight stabilized. A weighed amount of root material was placed into a 1-mm 15-cm long nylon mesh bag that was sub-sectioned into 0-7.5-cm and 7.5-15-cm depths prior to inserting

the root material. One decomposition bag was placed into each monolith and collected after one year. The roots were washed, dried at 60°C, and weighed. Breakdown was calculated as the difference between the final mass and the initial mass. Leaf litter breakdown was measured similarly. Senescent sawgrass leaves were collected from the same site, dried, inserted into one 1-mm mesh bag per monolith, and placed on the soil surface. Litter bags were collected at the end of one year. The decomposed litter was rinsed, dried, and weighed.

Soil elevation change. Prior to the beginning of the experiment, three 50-cm long rigid plastic rods were installed into each peat monolith down to the bottom of the bucket and labeled for repeated measurement. A reference soil surface height was recorded from the soil surface to the top of the rod. After the experiment began, the length from the soil surface to the top of each rod was recorded with a 40-cm long ruler. Elevation change was calculated as the difference between the measured rod length and the reference height.

Soil physicochemical properties. Soil properties were determined by taking one 2.4-cm diameter core down to 30-cm. Samples were weighed immediately after collection and after one week of drying at 60°C to calculate percent water content. Dried samples were also weighed to calculate dry bulk density (g cm^{-3}). The dried samples were subsequently ground, weighed, and analyzed for C, N¹⁰, and P¹¹ content.

Historic water level. At the brackish water field site, we took water level measurements every 15 min between October 2014 and August 2017 (Aqua TROLL 200, In Situ, Inc., Fort Collins, CO). Water level retrieved from a long-term gauge (USGS EDEN, NP6) was calibrated to water depth at the brackish water site by regressing two years of on-site water level measurements to water level measured on the same day by the EDEN gauge (BW water level = $1.104 * \text{NP6 EDEN gauge} + 17.778$, $r^2 = 0.827$). Water level at the BW site was then back-calculated back to 2001 using the equation above.

Field water collection. From October 2014 to August 2017, ambient surface water and porewater were collected monthly from the brackish water site that the monoliths for this experiment were extracted¹². Briefly, porewater was collected via sippers installed 15-cm into the soil. Porewater was extracted using a 140-mL syringe by placing suction on an airstone via a piece of tubing. Surface water was collected via grab samples. Both porewater and surface water was immediately sampled in the field for salinity (YSI Model 600 XL, Yellow Springs, OH). Detailed methods can be found in Wilson *et al.* (*in prep*).

Statistical analyses. Statistical analysis was performed using R (R Core Team 2016). Linear mixed models (Package “nlme”¹³) were used to examine the relationships among C flux, aboveground biomass, culm density, and elevation and the independent variables of salinity, inundation, and time (fixed factors). All organic matter input and breakdown rates, as well as soil bulk density, percent water, organic matter, C, N, and P content, were determined using a two-way ANOVA with salinity and inundation as the fixed

factors. Because of the split-plot, nested nature of our experimental design, each tank was set as a block (random factor), while inundation was nested within each block. All linear mixed models were assessed for temporal differences using the least squared means (LSMEANS), with date as a model effect (R package *lsmeans*¹⁴). All two-way ANOVAs were sub-tested with Tukey's post-hoc test to examine differences between treatments. Normality and homoscedasticity were tested by visually inspecting plotted residuals, and data was log-transformed in order to increase heteroscedasticity when necessary. Significance for all analyses was determined by an alpha level of 0.10 because of the nested nature of the design, the high variability between the monoliths, and the lack of available space to increase our replication power⁴.

Supplementary Results

Gas flux and aboveground biomass

Soil CO₂ efflux from the saltwater-amended monoliths increased significantly ($1.69 \pm 1.27 \mu\text{mol m}^{-2} \text{s}^{-1}$) compared to the ambient salinity monoliths ($0.35 \pm 0.29 \mu\text{mol m}^{-2} \text{s}^{-1}$) after salinity was initially raised from 10 to 15 ppt (LSMEANS, $t=-4.17$, $P=0.014$), but this effect diminished during the next month (Dec 2016) after salinity was raised from 15 to 20 ppt (LSMEANS, $t=0.26$, $P=0.807$; Fig. S1). Overall, elevated salinity had no significant effect on soil CO₂ efflux (Table S2). Drought caused significantly higher soil CO₂ efflux compared to the inundated monoliths, but there was no interacting effect of elevated salinity and drought (Table S2). When water was raised back to above the soil surface (Aug 2017), there was no difference in soil CO₂ efflux between the inundated and drought monoliths (LSMEANS, $t=-0.02$, $P=0.978$; Fig. S1).

Across the sampling year, short-term GEP rates ranged from $2.0 \mu\text{mol m}^{-2} \text{s}^{-1}$ (median for Salt.Exp in May 2017) to $11.2 \mu\text{mol m}^{-2} \text{s}^{-1}$ (median for Amb.Exp in Apr 2017; Fig. S2a). Rates of GEP were significantly lower with elevated salinity (Tables S2, S3). There was a significant effect of drought on GEP, however, this was only significant when comparing the ambient salinity monoliths, not the elevated salinity monoliths (Tables S2, S3). There was a large drop in GEP during the height of the drought (May-Jun) for the Amb.Exp monoliths (Fig. S2a).

Rates of ER_{CO_2} ranged from $0.9 \mu\text{mol m}^{-2} \text{s}^{-1}$ (median for Salt.Sub in Sep 2017) to $6.9 \mu\text{mol m}^{-2} \text{s}^{-1}$ (median for Amb.Exp in Apr 2017; Fig. S2b) and were significantly affected by both elevated salinity and drought (Table S2). Elevated salinity reduced mean ER_{CO_2} in both the submerged and drought monoliths, while drought significantly increased ER_{CO_2} (Table S3). Based on the difference between soil CO_2 efflux and ER_{CO_2} , plant respiration accounted for 80%, 74%, 79%, and 68% of total respiration for the Amb.Sub, Amb.Exp, Salt.Sub, and Salt.Exp monoliths, respectively.

Rates of NEP ranged from $-2.7 \mu\text{mol m}^{-2} \text{s}^{-1}$ (median for Salt.Exp in May 2017) to $8.8 \mu\text{mol m}^{-2} \text{s}^{-1}$ (median for Amb.Exp in Nov 2016; Fig. S2c). Despite much lower mean rates (Table S3), elevated salinity did not significantly affect NEP (Table S2). During the warmest part of the year (summer 2017), all the elevated salinity monoliths shifted from a net CO_2 sink to a net CO_2 source, with drought accelerating CO_2 loss from the marsh (Fig. S2c). Overall, drought did not affect NEP; however, there was an inundation by time effect (Table S2).

Modeled GEP strongly reflected the patterns seen with instantaneous GEP (Fig. S3a). Elevated salinity strongly suppressed GEP, while inundation level had no effect

(Table S2). Modeled ER_{CO_2} was enhanced with drought and suppressed with elevated salinity (Fig. S3b). Neither elevated salinity nor drought alone significantly affected modeled NEP, but there was a strong salinity by inundation effect (Table S2). When comparing the submerged treatments, elevated salinity caused significantly more C to be released to the atmosphere (Table 1). Under drought conditions, plant respiration (taken as the difference between soil CO_2 efflux and ER_{CO_2}) increased by $706 \text{ g C m}^{-2} \text{ yr}^{-1}$ with ambient salinity and only by $166 \text{ g C m}^{-2} \text{ yr}^{-1}$ with elevated salinity. This resulted in no calculated difference in modeled NEP between the ambient and elevated salinity treatments when experiencing drought (Table 1).

Aboveground biomass (g C m^{-2}) at the conclusion of the experiment was 140.1 ± 11.2 , 184.0 ± 36.7 , 73.1 ± 25.7 , and 147.3 ± 17.1 in the Amb.Sub, Amb.Exp, Salt.Sub, and Salt.Exp treatments, respectively. Elevated salinity led to significantly less biomass, while drought had no effect (Table S2). Culm density within the ambient salinity monoliths increased from 4.0 ± 0.5 and 4.7 ± 1.0 culms plot^{-1} at the beginning of the experiment to 6.0 ± 0.7 and 7.2 ± 1.2 culms plot^{-1} at the end of the experiment (Amb.Sub and Amb.Exp, respectively). Culm density within the elevated salinity monoliths remained relatively unchanged from the beginning (4.3 ± 0.8 and 7.2 ± 1.0 culms plot^{-1}) to the end of the experiment (3.0 ± 1.0 and 7.8 ± 1.3 culms plot^{-1} ; Salt.Sub and Salt.Exp, respectively). Culm density was not influenced by either elevated salinity or drought (Table S2). Rate of ANPP was also not affected by elevated salinity or drought (Table 1, S2).

Organic matter inputs and breakdown

We summarized organic matter inputs and breakdown in Table 1. Elevated salinity slowed decomposition in both the top 7.5-cm of soil ($F_{(1,19)}=5.29$, $P = 0.032$) and 7.5-15-cm depth ($F_{(1,19)}=5.43$, $P = 0.031$). Inundation accelerated breakdown in the 7.5-15-cm depth horizon ($F_{(1,19)}=7.65$, $P = 0.012$) but had no effect in the top 7.5-cm of soil ($F_{(1,19)}=0.28$, $P = 0.599$). Both elevated salinity ($F_{(1,15)}=8.70$, $P = 0.009$) and increased soil exposure ($F_{(1,15)}=65.86$, $P < 0.001$) significantly slowed leaf decomposition. Elevated salinity significantly reduced live root biomass measured at the end of the experiment ($F_{(1,19)}=36.52$, $P < 0.001$), but inundation did not have any effect ($F_{(1,19)}=0.181$, $P = 0.639$). Elevated salinity significantly reduced root ingrowth ($F_{(1,120)}=9.29$, $P = 0.006$), but inundation did not have any effect ($F_{(1,20)}=1.47$, $P = 0.239$). At the end of the experiment, live root biomass in soil down to 25-cm was 68.6 ± 18.2 , 107.5 ± 27.8 , 12.0 ± 7.7 , and 26.6 ± 7.9 g C m⁻² in the Amb.Sub, Amb.Exp, Salt.Sub, and Salt.Exp treatments, respectively. Elevated salinity significantly reduced live root biomass found at the end of the experiment ($F_{(1,19)}=36.52$, $P < 0.001$), but inundation did not have any effect ($F_{(1,19)}=0.181$, $P = 0.639$).

Soil properties

At the end of the experiment, there was no difference in soil bulk density and percent water among treatments (Table S4). Soil organic matter ($F_{(1,19)}=17.69$, $P < 0.001$), C ($F_{(1,19)}=12.92$, $P = 0.002$), and N ($F_{(1,19)}=6.77$, $P = 0.017$) content were all lower with elevated salinity (Table S4). Inundation had no effect on soil organic matter

($F_{(1,19)}=0.11$, $P = 0.737$), C ($F_{(1,19)}=0.03$, $P = 0.846$), and N ($F_{(1,19)}=0.30$, $P = 0.501$) content.

Elevation change

Over the duration of the experiment, soil elevation change was not affected by elevated salinity, but drought significantly increased elevation loss (Table S2). Elevation loss occurred in both the ambient and elevated salinity monoliths (Fig. 5). Over the duration of the experiment, the monoliths lost 2.9 ± 0.4 , 3.7 ± 0.4 , 3.0 ± 0.6 , and 4.4 ± 0.8 cm of elevation from the Amb.Sub, Amb.Exp, Salt.Sub, and Salt.Exp treatments, respectively.

CONCLUSION

Coastal wetlands and their capacity to store large amounts of carbon (C) in their soils, are threatened as a result of sea level rise (SLR). Sea level rise will cause saltwater to intrude into marshes, generating several forcing factors including: elevated salinity, greater inundation, and increased nutrients, that all have the potential to affect ecosystem structure and function. In coastal peat marshes such as the Everglades, even small changes in water chemistry or hydroperiod can substantially change the soil C balance and influence peat collapse. Here, I tested how saltwater intrusion would influence ecosystem structure and function within coastal wetlands, and how changes in ecosystem structure and function influenced peat collapse.

In chapter I, I show that 2 years of monthly pulses of saltwater produced contrasting results that depended on the initial salinity of the marsh. In the freshwater (FW) marsh, elevated salinity (~5 ppt) did not affect net ecosystem productivity (NEP) but did result in a decline in plant species richness and a decline in live roots found in the soil. At the brackish water (BW) site (ambient salinity ~10 ppt), I found no effects of elevated pulsed salinity (~20 ppt) on NEP when the marsh was inundated. However, when water fell below the soil surface, the BW marsh shifted from a C sink to a C source, and elevated salinity enhanced CO₂ efflux from the marsh by 3.6 times. In addition, there was a large loss of live roots in the soil with elevated salinity. Within the control plots, the BW site had significantly fewer live roots in the soil compared to the FW site.

In chapters II-IV, I used mesocosm experiments to test the press effects of saltwater intrusion in FW and BW marshes. In chapter II, I tested the effects of elevated salinity (~10 ppt) and increased phosphorus (P) loading in a FW marsh. Elevated salinity

alone had no effect on ecosystem productivity but led to a loss of live root. Elevated P alone significantly increased ecosystem productivity but had no effect on root growth. Because of this, plant biomass allocation shifted towards greater aboveground to belowground biomass. Combined, the effects of elevated salinity and P on ecosystem productivity changed temporally. Overall, elevated P had a greater subsidy effect on productivity than the stress effect of elevated salinity. However, elevated salinity began to have an inhibitory effect on ecosystem productivity after two years of continual exposure.

In chapter III, after finding that raising salinity to ~10 ppt in a FW marsh had no effect on ecosystem productivity (chapter II), I conducted a mesocosm experiment in which I raised salinity in monoliths from a BW marsh from ~10 ppt (ambient) to 20 ppt and subjected the monoliths to different inundation levels [submerged vs. exposed (water level 4-cm below soil surface)], to see if this would affect ecosystem productivity. Net ecosystem productivity declined by up to 9 times with elevated salinity, while more inundation had no effect on NEP. Soil CO₂ efflux was unaffected by elevated salinity and decreased with more inundation.

Finally, in chapter IV, based on results from the field data that showed that NEP was only affected by elevated salinity when water fell below the soil surface during drought (chapter I), I conducted a mesocosm experiment to test the combined effect of elevated salinity and drought on a BW marsh. Like chapter III, elevated salinity led to a significant decrease in NEP. Drought significantly increased soil CO₂ efflux. Under ambient salinity conditions (~10 ppt), I found a 2.9 ± 0.4 cm decrease in soil elevation after only one year, while elevating salinity did not significantly affect elevation loss.

Additionally, I measured elevation loss of 4.4 ± 0.8 cm after one year with combined elevated salinity and drought.

Given these findings, I can suggest hypotheses for the drivers and mechanisms of peat collapse. When freshwater marshes are first exposed to elevated salinity, aboveground productivity and NEP may be unaffected by elevated salinity and may actually increase with initial P exposure. Soil structure and integrity, however, are negatively affected by salt through a loss of live roots within the soil profile, leaving the peat vulnerable to collapse. This scenario explains the presence of live sawgrass “pedestals” in the brackish portions of the Everglades, where it appears that the surrounding soil has collapsed despite highly productive sawgrass plants. In fact, I found that soils within the BW portions of the Everglades may be experiencing a large rate (~ 3 cm yr⁻¹) of collapse under brackish water conditions. Exposing these brackish marshes to even greater increases in salinity further led to a net decline in soil C storage through reductions in NEP and root growth, but did not negatively affect elevation. Seasonal dry-down was a strong driver of elevation loss (~ 4.4 cm yr⁻¹) within BW soils and further exacerbated the peat collapse.

Although saltwater intrusion into freshwater wetlands may initially stimulate primary productivity through a P subsidy, the impact of elevated salinity on root and soil structure may ultimately be what matters to the survival or collapse of coastal peat marshes. Because seasonal dry-down can accelerate peat collapse, the restoration of flow regimes to the coastal Everglades has the potential to mitigate peat collapse. Increased water flows can mitigate peat collapse in two ways. First, enhanced freshwater delivery to coastal areas recharges aquifers and creates a stronger freshwater head that helps hold

back saltwater intrusion (Koch *et al.* 2015, Dessu *et al.* 2018). Second, longer periods of inundation, even with brackish water, can prevent strong, seasonal dry-down events from occurring (Sklar *et al.* 2001). This would greatly reduce groundwater intrusion of marine water into coastal marshes and prevent the acceleration of peat collapse. While it is unlikely that these marshes will ever recover to pre-collapsed conditions in the near future, enhanced water delivery has the potential to slow down collapse and allow for the recruitment and establishment of mangroves that help stabilize the soil (Jiang *et al.* 2014). However, given accelerating SLR and delays in the implementation of Comprehensive Everglades Restoration Plan projects, further collapse of peat marshes within the coastal Everglades can be expected. Understanding the drivers and mechanisms behind this collapse is urgently needed to inform management practices aimed at preventing peat collapse and the transformation of marsh habitat to open water ponds in the Everglades and other coastal peatlands (Delaune *et al.* 1994, Cahoon *et al.* 2003, Deegan *et al.* 2012).
